Springer

Springer Handbook of Crystal Growth

Springer Handbooks provide a concise compilation of approved key information on methods of research, general principles, and functional relationships in physical sciences and engineering. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of physical and technical information.

The volumes are designed to be useful as readable desk reference books to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

Springer Handbook of Crystal Growth

Govindhan Dhanaraj, Kullaiah Byrappa,
Vishwanath Prasad, Michael Dudley (Eds.)

With DVD-ROM, 1320 Figures, 134 in four color and 124 Tables

Preface

Over the years, many successful attempts have been made to describe the art and science of crystal growth, and many review articles, monographs, symposium volumes, and handbooks have been published to present comprehensive reviews of the advances made in this field. These publications are testament to the growing interest in both bulk and thin-film crystals because of their electronic, optical, mechanical, microstructural, and other properties, and their diverse scientific and technological applications. Indeed, most modern advances in semiconductor and optical devices would not have been possible without the development of many elemental, binary, ternary, and other compound crystals of varying properties and large sizes. The literature devoted to basic understanding of growth mechanisms, defect formation, and growth processes as well as the design of growth systems is therefore vast.

The objective of this Springer Handbook is to present the state of the art of selected topical areas of both bulk and thin-film crystal growth. Our goal is to make readers understand the basics of the commonly employed growth processes, materials produced, and defects generated. To accomplish this, we have selected more than 50 leading scientists, researchers, and engineers, and their many collaborators from 22 different countries, to write chapters on the topics of their expertise. These authors have written 52 chapters on the fundamentals of crystal growth and defect formation; bulk growth from the melt, solution, and vapor; epitaxial growth; modeling of growth processes and defects; and techniques of defect characterization, as well as some contemporary special topics.

This Springer Handbook is divided into seven parts. Part A presents the fundamentals: an overview of the growth and characterization techniques, followed by the state of the art of nucleation at surfaces, morphology of crystals grown from solutions, nucleation of dislocation during growth, and defect formation and morphology.

Part B is devoted to bulk growth from the melt, a method critical to producing large-size crystals. The

chapters in this part describe the well-known processes such as Czochralski, Kyropoulos, Bridgman, and floating zone, and focus specifically on recent advances in improving these methodologies such as application of magnetic fields, orientation of the growth axis, introduction of a pedestal, and shaped growth. They also cover a wide range of materials from silicon and III–V compounds to oxides and fluorides.

The third part, Part C of the book, focuses on solution growth. The various aspects of hydrothermal growth are discussed in two chapters, while three other chapters present an overview of the nonlinear and laser crystals, *KTP* and *KDP*. The knowledge on the effect of gravity on solution growth is presented through a comparison of growth on Earth versus in a microgravity environment.

The topic of Part D is vapor growth. In addition to presenting an overview of vapor growth, this part also provides details on vapor growth of silicon carbide, gallium nitride, aluminum nitride, and organic semiconductors. This is followed by chapters on epitaxial growth and thin films in Part E. The topics range from chemical vapor deposition to liquid-phase epitaxy to pulsed laser and pulsed electron deposition.

Modeling of both growth processes and defect formation is presented in Part F. These chapters demonstrate the direct correlation between the process parameters and quality of the crystal produced, including the formation of defects. The subsequent Part G presents the techniques that have been developed for crystalline material characterization and analysis. The chapters in Parts F and G demonstrate how well predictive tools and analytical techniques have helped the design and control of growth processes for better-quality crystals of large sizes.

The final Part H is devoted to some selected contemporary topics in this field, such as protein crystal growth, crystallization from gels, in situ structural studies, growth of single-crystal scintillation materials, photovoltaic materials, and wire-saw slicing of large crystals to produce wafers.

We hope this Springer Handbook will be useful to graduate students studying crystal growth and to re-

searchers, scientists, and engineers from academia and industry who are conducting or intend to conduct research in this field as well as those who grow crystals.

We would like to express our sincere thanks to Dr. Claus Acheron and Dr. Werner Skolaut of Springer and Ms Anne Strohbach of le-tex for their extraordinary efforts without which this handbook would not have taken its final shape.

We thank our authors for writing comprehensive chapters and having patience with us during the publication of this Handbook. One of the editors (GD) would

like to thank his family members and Dr. Kedar Gupta (CEO of ARC Energy) for their generous support and encouragement during the entire course of editing this handbook. Acknowledgements are also due to Peter Rudolf, David Bliss, Ishwara Bhat, and Partha Dutta for their help in editing Parts A, B, E, and H, respectively.

About the Editors

Govindhan Dhanaraj is the Manager of Crystal Growth Technologies at Advanced Renewable Energy Company (ARC Energy) at Nashua, New Hampshire (USA) focusing on the growth of large size sapphire crystals for LED lighting applications, characterization and related crystal growth furnace development. He received his PhD from the Indian Institute of Science, Bangalore and his Master of Science from Anna University (India). Immediately after his doctoral degree, Dr. Dhanaraj joined a National Laboratory, presently known as Rajaramanna Center for Advanced Technology in India, where he established an advanced Crystal Growth Laboratory for the growth of optical and laser crystals. Prior to joining ARC Energy, Dr. Dhanaraj served as a Research Professor at the Department of Materials Science and Engineering, Stony Brook University, NY, and also held a position of Research Assistant Professor at Hampton University, VA. During his 25 years of focused expertise in crystal growth research, he has developed optical, laser and semiconductor bulk crystals and SiC epitaxial films using solution, flux, Czochralski, Bridgeman, gel and vapor methods, and characterized them using x-ray topography, synchrotron topography, chemical etching and optical and atomic force microscopic techniques. He co-organized a symposium on Industrial Crystal Growth under the 17th American Conference on Crystal Growth and Epitaxy in conjunction with the 14th US Biennial Workshop on Organometallic Vapor Phase Epitaxy held at Lake Geneva, WI in 2009. Dr. Dhanaraj has delivered invited lectures and also served as session chairman in many crystal growth and materials science meetings. He has published over 100 papers and his research articles have attracted over 250 rich citations.

Kullaiah Byrappa received his Doctor's degree in Crystal Growth from the Moscow State University, Moscow in 1981. He is Professor of Materials Science, Head of the Crystal Growth Laboratory, and Director of the Internal Quality Assurance Cell of the University of Mysore, India. His current research is in crystal engineering of polyscale materials through novel solution processing routes, particularly covering hydrothermal, solvothermal and supercritical methods. Professor Byrappa has co-authored the Handbook of Hydrothermal Technology, and edited 4 books as well as two special editions of Journal of Materials Science, and published 180 research papers including 26 invited reviews and book chapters on various aspects of novel routes of solution processing. Professor Byrappa has delivered over 60 keynote and invited lectures at International Conferences, and several hundreds of colloquia and seminars at various institutions around the world. He has also served as chair and co-chair for numerous international conferences. He is a Fellow of the World Academy of Ceramics. Professor Byrappa is serving in several international committees and commissions related to crystallography, crystal growth, and materials science. He is the Founder Secretary of the International Solvothermal and Hydrothermal Association. Professor Byrappa is a recipient of several awards such as the Sir C.V. Raman Award, Materials Research Society of India Medal, and the Golden Jubilee Award of the University of Mysore.

Vishwanath "Vish" Prasad is the Vice President for Research and Economic Development and Professor of Mechanical and Energy Engineering at the University of North Texas (UNT), one of the largest university in the state of Texas. He received his PhD from the University of Delaware (USA), his Masters of Technology from the Indian Institute of Technology, Kanpur, and his bachelor's from Patna University in India all in Mechanical Engineering. Prior to joining UNT in 2007, Dr. Prasad served as the Dean at Florida International University (FIU) in Miami, where he also held the position of Distinguished Professor of Engineering. Previously, he has served as a Leading Professor of Mechanical Engineering at Stony Brook University, New York, as an Associate Professor and Assistant Professor at Columbia University. He has received many special recognitions for his contributions to engineering education. Dr. Prasad's research interests include thermo-fluid sciences, energy systems, electronic materials, and computational materials processing. He has published over 200 articles, edited/co-edited several books and organized numerous conferences, symposia, and workshops. He serves as the lead editor of the Annual Review of Heat Transfer. In the past, he has served as an Associate Editor of the ASME Journal of Heat. Dr. Prasad is an elected Fellow of the American Society of Mechanical Engineers (ASME), and has served as a member of the USRA Microgravity Research Council. Dr. Prasad's research has focused on bulk growth of silicon, III-V compounds, and silicon carbide; growth of large diameter Si tube; design of crystal growth systems; and sputtering and chemical vapor deposition of thin films. He is also credited to initiate research on wire saw cutting of large crystals to produce wafers with much reduced material loss. Dr. Prasad's research has been well funded by US National Science Foundation (NSF), US Department of Defense, US Department of Energy, and industry.

Michael Dudley received his Doctoral Degree in Engineering from Warwick University, UK, in 1982. He is Professor and Chair of the Materials Science and Engineering Department at Stony Brook University, New York, USA. He is director of the Stony Brook Synchrotron Topography Facility at the National Synchrotron Light Source at Brookhaven National Laboratory, Upton New York. His current research focuses on crystal growth and characterization of defect structures in single crystals with a view to determining their origins. The primary technique used is synchrotron topography which enables analysis of defects and generalized strain fields in single crystals in general, with particular emphasis on semiconductor, optoelectronic, and optical crystals. Establishing the relationship between crystal growth conditions and resulting defect distributions is a particular thrust area of interest to Dudley, as is the correlation between electronic/optoelectronic device performance and defect distribution. Other techniques routinely used in such analysis include transmission electron microscopy, high resolution triple-axis x-ray diffraction, atomic force microscopy, scanning electron microscopy, Nomarski optical microscopy, conventional optical microscopy, IR microscopy and fluorescent laser scanning confocal microscopy. Dudley's group has played a prominent role in the development of SiC and AlN growth, characterizing crystals grown by many of the academic and commercial entities involved enabling optimization of crystal quality. He has co-authored some 315 refereed articles and 12 book chapters, and has edited 5 books. He is currently a member of the Editorial Board of Journal of Applied Physics and Applied Physics Letters and has served as Chair or Co-Chair for numerous international conferences.

List of Abbreviations	XXXI
------------------------------------	-------------

Part A Fundamentals of Crystal Growth and Defect Formation

1 Crystal Growth Techniques and Characterization: An Overview	
<i>Govindhan Dhanaraj, Kullaiah Byrappa, Vishwanath (Vish) Prasad, Michael Dudley</i>	3
1.1 Historical Developments	3
1.2 Theories of Crystal Growth	4
1.3 Crystal Growth Techniques	6
1.4 Crystal Defects and Characterization	11
References	15
2 Nucleation at Surfaces	
<i>Ivan V. Markov</i>	17
2.1 Equilibrium Crystal–Ambient Phase	18
2.2 Work for Nucleus Formation	24
2.3 Rate of Nucleation	28
2.4 Saturation Nucleus Density	35
2.5 Second–Layer Nucleation in Homoepitaxy	38
2.6 Mechanism of Clustering in Heteroepitaxy	43
2.7 Effect of Surfactants on Nucleation	45
2.8 Conclusions and Outlook	48
References	48
3 Morphology of Crystals Grown from Solutions	
<i>Francesco Abbona, Dino Aquilano</i>	53
3.1 Equilibrium Shape	55
3.2 The Theoretical Growth Shape	64
3.3 Factors Influencing the Crystal Habit	71
3.4 Surface Structure	72
3.5 Crystal Defects	73
3.6 Supersaturation – Growth Kinetics	73
3.7 Solvent	75
3.8 Impurities	78
3.9 Other Factors	84
3.10 Evolution of Crystal Habit	85
3.11 A Short Conclusion	86
3.A Appendix	86
References	87

4 Generation and Propagation of Defects During Crystal Growth
Helmut Klapper 93

4.1 Overview 94

4.2 Inclusions 95

4.3 Striations and Growth Sectors 101

4.4 Dislocations 107

4.5 Twinning 120

4.6 Perfection of Crystals Grown Rapidly from Solution 125

References 127

5 Single Crystals Grown Under Unconstrained Conditions
Ichiro Sunagawa 133

5.1 Background 134

5.2 Smooth and Rough Interfaces: Growth Mechanism and Morphology 136

5.3 Surface Microtopography 139

5.4 Growth Forms of Polyhedral Crystals 143

5.5 Internal Morphology 146

5.6 Perfection of Single Crystals 152

References 156

6 Defect Formation During Crystal Growth from the Melt
Peter Rudolph 159

6.1 Overview 159

6.2 Point Defects 163

6.3 Dislocations 176

6.4 Second-Phase Particles 188

6.5 Faceting 191

6.6 Twinning 193

6.7 Summary 194

References 195

Part B Crystal Growth from Melt Techniques

7 Indium Phosphide: Crystal Growth and Defect Control by Applying Steady Magnetic Fields
David F. Bliss 205

7.1 Historical Overview 205

7.2 Magnetic Liquid-Encapsulated Growth 206

7.3 Magnetic Field Interactions with the Melt 209

7.4 Dislocation Density 216

7.5 Magnetic Field Effects on Impurity Segregation 220

7.6 Optical Characterization of InP:Fe 224

7.7 Summary 226

References 227

8 Czochralski Silicon Single Crystals for Semiconductor and Solar Cell Applications	
<i>Koichi Kakimoto</i>	231
8.1 Silicon Single Crystals for LSIs and Solar Applications	232
8.2 Control of Crystal Defects in Czochralski Silicon	237
8.3 Growth and Characterization of Silicon Multicrystal for Solar Cell Applications	239
8.4 Summary	240
References	241
9 Czochralski Growth of Oxide Photorefractive Crystals	
<i>Ernesto Diéguez, Jose Luis Plaza, Mohan D. Aggarwal, Ashok K. Batra</i>	245
9.1 Background	246
9.2 Crystal Growth	246
9.3 Design and Development of Czochralski Growth System	247
9.4 Growth of Lithium Niobate Crystals and Its Characteristics	252
9.5 Other Oxide Photorefractive Crystals	262
9.6 Growth of Sillenite Crystals and Its Characteristics	264
9.7 Conclusions	273
References	273
10 Bulk Crystal Growth of Ternary III–V Semiconductors	
<i>Partha S. Dutta</i>	281
10.1 III–V Ternary Semiconductors	282
10.2 Need for Ternary Substrates	283
10.3 Criteria for Device-Grade Ternary Substrates	284
10.4 Introduction to Bridgman Crystal Growth Techniques	286
10.5 Overview of III–V Binary Crystal Growth Technologies	292
10.6 Phase Equilibria for Ternary Compounds	300
10.7 Alloy Segregation in Ternary Semiconductors	302
10.8 Crack Formation in Ternary Crystals	304
10.9 Single-Crystalline Ternary Seed Generation Processes	308
10.10 Solute Feeding Processes for Homogeneous Alloy Growth	311
10.11 Role of Melt–Solid Interface Shapes	318
10.12 Conclusion	321
References	321
11 Growth and Characterization of Antimony-Based Narrow-Bandgap III–V Semiconductor Crystals for Infrared Detector Applications	
<i>Vijay K. Dixit, Handady L. Bhat</i>	327
11.1 Importance of Antimony-Based Semiconductors	329
11.2 Phase Diagrams	330
11.3 Crystal Structure and Bonding	331
11.4 Material Synthesis and Purification	333

11.5	Bulk Growth of InSb	334
11.6	Structural Properties of InSb, InAs _x Sb _{1-x} , and InBi _x Sb _{1-x}	340
11.7	Physical Properties of InSb, InAs _x Sb _{1-x} , and InBi _x Sb _{1-x}	346
11.8	Applications	357
11.9	Concluding Remarks and Future Outlook	359
	References	360
12	Crystal Growth of Oxides by Optical Floating Zone Technique	
	<i>Hanna A. Dabkowska, Antoni B. Dabkowski</i>	367
12.1	Historical Notes	367
12.2	Optical Floating Zone Technique – Application for Oxides	368
12.3	Optical Floating Zone and Traveling Solvent Crystal Growth Techniques	369
12.4	Advantages and Limitations of the Floating Zone Techniques	370
12.5	Optical Floating Zone Furnaces	371
12.6	Experimental Details of Ceramics and Rod Preparation for OFZT	372
12.7	Stable Growth of Congruently and Incongruently Melting Oxides	373
12.8	Constitutional Supercooling and Crystallization Front Stability	375
12.9	Crystal Growth Termination and Cooling	377
12.10	Characterization of Crystals Grown by the OFZ Technique	377
12.11	Determination of Defects in Crystals – The Experimental Approach ..	380
12.12	Details of Conditions for Growth of Selected Oxide Single Crystals by OFZ and TSFZ Methods	383
12.13	Conclusions	386
	References	386
13	Laser-Heated Pedestal Growth of Oxide Fibers	
	<i>Marcello R.B. Andreeta, Antonio Carlos Hernandes</i>	393
13.1	Fiber-Pulling Research	394
13.2	The Laser-Heated Pedestal Growth Technique	399
13.3	Fundamentals	402
13.4	Fiber Growth Aspects	409
13.5	Conclusions	418
	References	419
14	Synthesis of Refractory Materials by Skull Melting Technique	
	<i>Vyacheslav V. Osiko, Mikhail A. Borik, Elena E. Lomonova</i>	433
14.1	Overview	433
14.2	Techniques for Growth of Single Crystals in a Cold Crucible	435
14.3	Growth of Single Crystals Based on Zirconium Dioxide	443
14.4	Glass Synthesis by Skull Melting in a Cold Crucible	465
14.5	Conclusion	469
	References	469

15 Crystal Growth of Laser Host Fluorides and Oxides

<i>Hongjun Li, Jun Xu</i>	479
15.1 Crystal Growth of Laser Fluorides and Oxides from Melt	479
15.2 Laser Crystal Defects	487
15.3 Crystal Growth Techniques Characterization	501
References	503

16 Shaped Crystal Growth

<i>Vitali A. Tatartchenko</i>	509
16.1 Definitions and Scope of Discussion: SCG by CST	510
16.2 DSC – Basis of SCG by CST	512
16.3 SA and SCG by CZT	517
16.4 SA and SCG by VT	519
16.5 SA and SCG by FZT	522
16.6 TPS Capillary Shaping.....	522
16.7 TPS Sapphire Growth	539
16.8 TPS Silicon Growth	546
16.9 TPS Metals Growth	551
16.10 TPS Peculiarities	552
References	552

Part C Solution Growth of Crystals**17 Bulk Single Crystals Grown from Solution on Earth and in Microgravity**

<i>Mohan D. Aggarwal, Ashok K. Batra, Ravindra B. Lal, Benjamin G. Penn, Donald O. Frazier</i>	559
17.1 Crystallization: Nucleation and Growth Kinetics	561
17.2 Low-Temperature Solution Growth	566
17.3 Solution Growth by Temperature Lowering	567
17.4 Triglycine Sulfate Crystal Growth: A Case Study	574
17.5 Solution Growth of Triglycine Sulfate Crystals in Microgravity	582
17.6 Protein Crystal Growth	592
17.7 Concluding Remarks	594
References	594

18 Hydrothermal Growth of Polyscale Crystals

<i>Kullaiah Byrappa</i>	599
18.1 History of Hydrothermal Growth of Crystals	603
18.2 Thermodynamic Basis of the Hydrothermal Growth of Crystals	606
18.3 Apparatus Used in the Hydrothermal Growth of Crystals	615
18.4 Hydrothermal Growth of Some Selected Crystals.....	620
18.5 Hydrothermal Growth of Fine Crystals.....	634

18.6	Hydrothermal Growth of Nanocrystals	637
18.7	Concluding Remarks	640
18.A	Appendix	641
	References	646
19	Hydrothermal and Ammonothermal Growth of ZnO and GaN	
	<i>Michael J. Callahan, Qi-Sheng Chen</i>	655
19.1	Overview of Hydrothermal and Ammonothermal Growth of Large Crystals	657
19.2	Requirements for Growth of Large, Low-Defect Crystals	661
19.3	Physical and Mathematical Models	666
19.4	Process Simulations	669
19.5	Hydrothermal Growth of ZnO Crystals	674
19.6	Ammonothermal GaN	681
19.7	Conclusion	685
	References	685
20	Stoichiometry and Domain Structure of KTP-Type Nonlinear Optical Crystals	
	<i>Michael Roth</i>	691
20.1	Background	691
20.2	Stoichiometry and Ferroelectric Phase Transitions	697
20.3	Growth-Induced Ferroelectric Domains	703
20.4	Artificial Domain Structures	708
20.5	Nonlinear Optical Crystals	713
	References	716
21	High-Temperature Solution Growth: Application to Laser and Nonlinear Optical Crystals	
	<i>Joan J. Carvajal, Maria Cinta Pujol, Francesc Díaz</i>	725
21.1	Basics	726
21.2	High-Temperature Solution Growth	731
21.3	Growth of Bulk Laser and NLO Single Crystals by the TSSG Method	736
21.4	Liquid-Phase Epitaxy: Growth of Epitaxial Films of Laser and NLO Materials	746
	References	752
22	Growth and Characterization of KDP and Its Analogs	
	<i>Sheng-Lai Wang, Xun Sun, Xu-Tang Tao</i>	759
22.1	Background	759
22.2	Mechanism and Kinetics of Crystallization	761
22.3	Growth Techniques for Single Crystals	769
22.4	Effect of Growth Conditions on Defects of Crystals	776
22.5	Investigations on Crystal Quality	783
	References	789

Part D Crystal Growth from Vapor

23 Growth and Characterization of Silicon Carbide Crystals	
<i>Govindhan Dhanaraj, Balaji Raghothamachar, Michael Dudley</i>	797
23.1 Silicon Carbide – Background and History	797
23.2 Vapor Growth	799
23.3 High-Temperature Solution Growth	801
23.4 Industrial Bulk Growth by Seed Sublimation	802
23.5 Structural Defects and Their Configurations	805
23.6 Concluding Remarks	816
References	817
24 AlN Bulk Crystal Growth by Physical Vapor Transport	
<i>Rafael Dalmau, Zlatko Sitar</i>	821
24.1 PVT Crystal Growth	822
24.2 High-Temperature Materials Compatibility	825
24.3 Self-Seeded Growth of AlN Bulk Crystals	827
24.4 Seeded Growth of AlN Bulk Crystals	829
24.5 Characterization of High-Quality Bulk Crystals.....	832
24.6 Conclusions and Outlook.....	839
References	839
25 Growth of Single-Crystal Organic Semiconductors	
<i>Christian Kloc, Theo Siegrist, Jens Pflaum</i>	845
25.1 Basics	845
25.2 Theory of Nucleation and Crystal Growth	847
25.3 Organic Materials of Interest for Semiconducting Single Crystals	848
25.4 Pregrowth Purification.....	850
25.5 Crystal Growth.....	854
25.6 Quality of Organic Semiconducting Single Crystals	862
25.7 Organic Single-Crystalline Field-Effect Transistors	863
25.8 Conclusions.....	864
References	865
26 Growth of III-Nitrides with Halide Vapor Phase Epitaxy (HVPE)	
<i>Carl Hemmingsson, Bo Monemar, Yoshinao Kumagai, Akinori Koukitu</i>	869
26.1 Growth Chemistry and Thermodynamics	869
26.2 HVPE Growth Equipment.....	872
26.3 Substrates and Templates for Bulk GaN Growth.....	875
26.4 Substrate Removal Techniques	879
26.5 Doping Techniques for GaN in HVPE.....	882
26.6 Defect Densities, Dislocations, and Residual Impurities	883
26.7 Some Important Properties of HVPE-Grown Bulk GaN Material	887
26.8 Growth of AlN by HVPE: Some Preliminary Results	888
26.9 Growth of InN by HVPE: Some Preliminary Results	890
References	891

27 Growth of Semiconductor Single Crystals from Vapor Phase	
<i>Ramasamy Dhanasekaran</i>	897
27.1 Classifications of Vapor Growth	899
27.2 Chemical Vapor Transport – Transport Kinetics	901
27.3 Thermodynamic Considerations	905
27.4 Growth of II–VI Compound Semiconductors by CVT	912
27.5 Growth of Nanomaterial from Vapor Phase	916
27.6 Growth of I–III–VI ₂ Compounds	917
27.7 Growth of GaN by VPE	925
27.8 Conclusion	929
References	930

Part E Epitaxial Growth and Thin Films

28 Epitaxial Growth of Silicon Carbide by Chemical Vapor Deposition	
<i>Ishwara B. Bhat</i>	939
28.1 Polytypes of Silicon Carbide	941
28.2 Defects in SiC	942
28.3 Epitaxial Growth of Silicon Carbide	944
28.4 Epitaxial Growth on Patterned Substrates	952
28.5 Conclusions	961
References	961

29 Liquid-Phase Electroepitaxy of Semiconductors	
<i>Sadik Dost</i>	967
29.1 Background	967
29.2 Early Theoretical and Modeling Studies	971
29.3 Two-Dimensional Continuum Models	977
29.4 LPEE Growth Under a Stationary Magnetic Field	978
29.5 Three-Dimensional Simulations	981
29.6 High Growth Rates in LPEE: Electromagnetic Mobility	992
References	996

30 Epitaxial Lateral Overgrowth of Semiconductors	
<i>Zbigniew R. Zytewicz</i>	999
30.1 Overview	1000
30.2 Mechanism of Epitaxial Lateral Overgrowth from the Liquid Phase	1002
30.3 Dislocations in ELO Layers	1011
30.4 Strain in ELO Layers	1016
30.5 Recent Progress in Lateral Overgrowth of Semiconductor Structures	1026
30.6 Concluding Remarks	1034
References	1035

31 Liquid-Phase Epitaxy of Advanced Materials	
<i>Christine F. Klemenz Rivenbark</i>	1041
31.1 Historical Development of LPE	1042
31.2 Fundamentals of LPE and Solution Growth	1042
31.3 Requirements for Liquid-Phase Epitaxy	1044
31.4 Developing New Materials: On the Choice of the Epitaxial Deposition Method	1044
31.5 LPE of High-Temperature Superconductors	1046
31.6 LPE of Calcium Gallium Germanates.....	1055
31.7 Liquid-Phase Epitaxy of Nitrides	1059
31.8 Conclusions	1063
References	1064
32 Molecular-Beam Epitaxial Growth of HgCdTe	
<i>James W. Garland, Sivalingam Sivananthan</i>	1069
32.1 Overview	1070
32.2 Theory of MBE Growth	1073
32.3 Substrate Materials	1076
32.4 Design of the Growth Hardware	1088
32.5 In situ Characterization Tools for Monitoring and Controlling the Growth	1090
32.6 Nucleation and Growth Procedure.....	1101
32.7 Dopants and Dopant Activation.....	1104
32.8 Properties of HgCdTe Epilayers Grown by MBE	1107
32.9 HgTe/CdTe Superlattices	1112
32.10 Architectures of Advanced IR Detectors	1115
32.11 IR Focal-Plane Arrays (FPAs)	1118
32.12 Conclusions	1119
References	1121
33 Metalorganic Vapor-Phase Epitaxy of Diluted Nitrides and Arsenide Quantum Dots	
<i>Udo W. Pohl</i>	1133
33.1 Principle of MOVPE.....	1133
33.2 Diluted Nitride InGaAsN Quantum Wells	1137
33.3 InAs/GaAs Quantum Dots.....	1142
33.4 Concluding Remarks	1148
References	1148
34 Formation of SiGe Heterostructures and Their Properties	
<i>Yasuhiro Shiraki, Akira Sakai</i>	1153
34.1 Background	1153
34.2 Band Structures of Si/Ge Heterostructures	1154
34.3 Growth Technologies	1156
34.4 Surface Segregation	1157
34.5 Critical Thickness	1161
34.6 Mechanism of Strain Relaxation	1163

34.7	Formation of Relaxed SiGe Layers	1165
34.8	Formation of Quantum Wells, Superlattices, and Quantum Wires	1173
34.9	Dot Formation	1177
34.10	Concluding Remarks and Future Prospects	1184
	References	1184
35	Plasma Energetics in Pulsed Laser and Pulsed Electron Deposition	
	<i>Mikhail D. Strikovski, Jeonggoo Kim, Solomon H. Kolagani</i>	1193

List of Abbreviations

μ -PD	micro-pulling-down
1S-ELO	one-step ELO structure
2-D	two-dimensional
2-DNG	two-dimensional nucleation growth
2S-ELO	double layer ELO
3-D	three-dimensional
4T	quaterthiophene
6T	sexithienyl
8MR	eight-membered ring
8T	hexathiophene

A

a-Si	amorphous silicon
A/D	analogue-to-digital
AA	additional absorption
AANP	2-adamantylamino-5-nitropyridine
AAS	atomic absorption spectroscopy
AB	Abrahams and Burocchi
ABES	absorption-edge spectroscopy
AC	alternate current
ACC	annular capillary channel
ACRT	accelerated crucible rotation technique
ADC	analog-to-digital converter
ADC	automatic diameter control
ADF	annular dark field
ADP	ammonium dihydrogen phosphate
AES	Auger electron spectroscopy
AFM	atomic force microscopy
ALE	arbitrary Lagrangian Eulerian
ALE	atomic layer epitaxy
ALUM	aluminum potassium sulfate
ANN	artificial neural network
AO	acoustooptic
AP	atmospheric pressure
APB	antiphase boundaries
APCF	advanced protein crystallization facility
APD	avalanche photodiode
APPLN	aperiodic poled LN
APS	Advanced Photon Source
AR	antireflection
AR	aspect ratio
ART	aspect ratio trapping
ATGSP	alanine doped triglycine sulfo-phosphate
AVT	angular vibration technique

B

BA	Born approximation
BAC	band anticrossing

BBO	BaB ₂ O ₄
BCF	Burton–Cabrera–Frank
BCT	Ba _{0.77} Ca _{0.23} TiO ₃
BCTi	Ba _{1-x} Ca _x TiO ₃
BE	bound exciton
BF	bright field
BFDH	Bravais–Friedel–Donnay–Harker
BGO	Bi ₁₂ GeO ₂₀
BIBO	BiB ₃ O ₆
BLIP	background-limited performance
BMO	Bi ₁₂ MO ₂₀
BN	boron nitride
BOE	buffered oxide etch
BPD	basal-plane dislocation
BPS	Burton–Prim–Slichter
BPT	bipolar transistor
BS	Bridgman–Stockbarger
BSCCO	Bi–Sr–Ca–Cu–O
BSF	bounding stacking fault
BSO	Bi ₂₀ SiO ₂₀
BTO	Bi ₁₂ TiO ₂₀
BU	building unit
BaREF	barium rare-earth fluoride
BiSCCO	Bi ₂ Sr ₂ CaCu ₂ O _n

C

C–V	capacitance–voltage
CALPHAD	calculation of phase diagram
CBED	convergent-beam electron diffraction
CC	cold crucible
CCC	central capillary channel
CCD	charge-coupled device
CCVT	contactless chemical vapor transport
CD	convection diffusion
CE	counterelectrode
CFD	computational fluid dynamics
CFD	cumulative failure distribution
CFMO	Ca ₂ FeMoO ₆
CFS	continuous filtration system
CGG	calcium gallium germanate
CIS	copper indium diselenide
CL	cathode-ray luminescence
CL	cathodoluminescence
CMM	coordinate measuring machine
CMO	CaMoO ₄
CMOS	complementary metal–oxide–semiconductor
CMP	chemical–mechanical polishing
CMP	chemomechanical polishing

COD	calcium oxalate dihydrate
COM	calcium oxalate-monohydrate
COP	crystal-originated particle
CP	critical point
CPU	central processing unit
CRSS	critical-resolved shear stress
CSMO	$\text{Ca}_{1-x}\text{Sr}_x\text{MoO}_3$
CST	capillary shaping technique
CST	crystalline silico titanate
CT	computer tomography
CTA	CsTiOAsO_4
CTE	coefficient of thermal expansion
CTF	contrast transfer function
CTR	crystal truncation rod
CV	Cabrera–Vermilyea
CVD	chemical vapor deposition
CVT	chemical vapor transport
CW	continuous wave
CZ	Czochralski
CZT	Czochralski technique

D

D/A	digital to analog
DBR	distributed Bragg reflector
DC	direct current
DCAM	diffusion-controlled crystallization apparatus for microgravity
DCCZ	double crucible CZ
DCPD	dicalcium-phosphate dihydrate
DCT	dichlorotetracene
DD	dislocation dynamics
DESY	Deutsches Elektronen Synchrotron
DF	dark field
DFT	density function theory
DFW	defect free width
DGS	diglycine sulfate
DI	deionized
DIA	diamond growth
DIC	differential interference contrast
DICM	differential interference contrast microscopy
DKDP	deuterated potassium dihydrogen phosphate
DLATGS	deuterated L-alanine-doped triglycine sulfate
DLTS	deep-level transient spectroscopy
DMS	discharge mass spectroscopy
DNA	deoxyribonucleic acid
DOE	Department of Energy
DOS	density of states
DPH-BDS	2,6-diphenylbenzo[1,2- <i>b</i> :4,5- <i>b'</i>]diselenophene
DPPH	2,2-diphenyl-1-picrylhydrazyl
DRS	dynamic reflectance spectroscopy

DS	directional solidification
DSC	differential scanning calorimetry
DSE	defect-selective etching
DSL	diluted Sirtl with light
DTA	differential thermal analysis
DTGS	deuterated triglycine sulfate
DVD	digital versatile disk
DWBA	distorted-wave Born approximation
DWELL	dot-in-a-well

E

EADM	extended atomic distance mismatch
EALFZ	electrical-assisted laser floating zone
EB	electron beam
EBIC	electron-beam-induced current
ECE	end chain energy
ECR	electron cyclotron resonance
EDAX	energy-dispersive x-ray analysis
EDMR	electrically detected magnetic resonance
EDS	energy-dispersive x-ray spectroscopy
EDT	ethylene dithiotetrathiafulvalene
EDTA	ethylene diamine tetraacetic acid
EELS	electron energy-loss spectroscopy
EFG	edge-defined film-fed growth
EFTEM	energy-filtered transmission electron microscopy
ELNES	energy-loss near-edge structure
ELO	epitaxial lateral overgrowth
EM	electromagnetic
EMA	effective medium theory
EMC	electromagnetic casting
EMCZ	electromagnetic Czochralski
EMF	electromotive force
ENDOR	electron nuclear double resonance
EO	electrooptic
EP	EaglePicher
EPD	etch pit density
EPMA	electron microprobe analysis
EPR	electron paramagnetic resonance
erfc	error function
ES	equilibrium shape
ESP	edge-supported pulling
ESR	electron spin resonance
EVA	ethyl vinyl acetate

F

F	flat
FAM	free abrasive machining
FAP	$\text{Ca}_5(\text{PO}_4)_3\text{F}$
FCA	free carrier absorption
fcc	face-centered cubic
FEC	full encapsulation Czochralski

FEM	finite element method
FES	fluid experiment system
FET	field-effect transistor
FFT	fast Fourier transform
FIB	focused ion beam
FOM	figure of merit
FPA	focal-plane array
FPE	Fokker–Planck equation
FSLI	femtosecond laser irradiation
FT	flux technique
FTIR	Fourier-transform infrared
FWHM	full width at half-maximum
FZ	floating zone
FZT	floating zone technique

G

GAME	gel acupuncture method
GDMS	glow-discharge mass spectrometry
GE	General Electric
GGG	gadolinium gallium garnet
GNB	geometrically necessary boundary
GPIB	general purpose interface bus
GPMD	geometric partial misfit dislocation
GRI	growth interruption
GRIIRA	green-radiation-induced infrared absorption
GS	growth sector
GSAS	general structure analysis software
GSGG	Gd ₃ Sc ₂ Ga ₃ O ₁₂
GSMBE	gas-source molecular-beam epitaxy
GSO	Gd ₂ SiO ₅
GU	growth unit

H

HA	hydroxyapatite
HAADF	high-angle annular dark field
HAADF-STEM	high-angle annular dark field in scanning transmission electron microscope
HAP	hydroxyapatite
HB	horizontal Bridgman
HBM	Hottinger Baldwin Messtechnik GmbH
HBT	heterostructure bipolar transistor
HBT	horizontal Bridgman technique
HDPCG	high-density protein crystal growth
HE	high energy
HEM	heat-exchanger method
HEMT	high-electron-mobility transistor
HF	hydrofluoric acid
HGF	horizontal gradient freezing
HH	heavy-hole
HH-PCAM	handheld protein crystallization apparatus for microgravity
HIV	human immunodeficiency virus

HIV-AIDS	human immunodeficiency virus–acquired immunodeficiency syndrome
HK	high potassium content
HLA	half-loop array
HLW	high-level waste
HMDS	hexamethyldisilane
HMT	hexamethylene tetramine
HNP	high nitrogen pressure
HOE	holographic optical element
HOLZ	higher-order Laue zone
HOMO	highest occupied molecular orbital
HOPG	highly oriented pyrolytic graphite
HOT	high operating temperature
HP	Hartman–Perdok
HPAT	high-pressure ammonothermal technique
HPHT	high-pressure high-temperature
HRTEM	high-resolution transmission electron microscopy
HRXRD	high-resolution x-ray diffraction
HSXPD	hemispherically scanned x-ray photoelectron diffraction
HT	hydrothermal
HTS	high-temperature solution
HTSC	high-temperature superconductor
HVPE	halide vapor-phase epitaxy
HVPE	hydride vapor-phase epitaxy
HWC	hot-wall Czochralski
HZM	horizontal ZM

I

IBAD	ion-beam-assisted deposition
IBE	ion beam etching
IC	integrated circuit
IC	ion chamber
ICF	inertial confinement fusion
ID	inner diameter
ID	inversion domain
IDB	incidental dislocation boundary
IDB	inversion domain boundary
IF	identification flat
IG	inert gas
IK	intermediate potassium content
ILHPG	indirect laser-heated pedestal growth
IML-1	International Microgravity Laboratory
IMPATT	impact ionization avalanche transit-time
IP	image plate
IPA	isopropyl alcohol
IR	infrared
IRFPA	infrared focal plane array
IS	interfacial structure
ISS	ion-scattering spectroscopy
ITO	indium-tin oxide
ITTFA	iterative target transform factor analysis
IVPE	iodine vapor-phase epitaxy

J		LGS	$\text{La}_3\text{Ga}_5\text{SiO}_{14}$
JDS	joint density of states	LGT	$\text{La}_3\text{Ga}_{5.5}\text{Ta}_{0.5}\text{O}_{14}$
JFET	junction FET	LH	light hole
K		LHFB	L-histidine tetrafluoroborate
K	kinked	LHPG	laser-heated pedestal growth
KAP	potassium hydrogen phthalate	LID	laser-induced damage
KDP	potassium dihydrogen phosphate	LK	low potassium content
KGW	$\text{KY}(\text{WO}_4)_2$	LLNL	Lawrence Livermore National Laboratory
KGdP	$\text{KGd}(\text{PO}_3)_4$	LLO	laser lift-off
KLYF	KLiYF_5	LLW	low-level waste
KM	Kubota–Mullin	LN	LiNbO_3
KMC	kinetic Monte Carlo	LP	low pressure
KN	KNbO_3	LPD	liquid-phase diffusion
KNP	$\text{KNd}(\text{PO}_3)_4$	LPE	liquid-phase epitaxy
KPZ	Kardar–Parisi–Zhang	LPEE	liquid-phase electroepitaxy
KREW	$\text{KRE}(\text{WO}_4)_2$	LPS	$\text{Lu}_2\text{Si}_2\text{O}_7$
KTA	potassium titanyl arsenate	LSO	Lu_2SiO_5
KTN	potassium niobium tantalate	LST	laser scattering tomography
KTP	potassium titanyl phosphate	LST	local shaping technique
KTa	KTaO_3	LT	low-temperature
KTaN	$\text{KTa}_{1-x}\text{Nb}_x\text{O}_3$	LTa	LiTaO_3
KYF	KYF_4	LUMO	lowest unoccupied molecular orbital
KYW	$\text{KY}(\text{WO}_4)_2$	LVM	local vibrational mode
L		LWIR	long-wavelength IR
LACBED	large-angle convergent-beam diffraction	LY	light yield
LAFB	L-arginine tetrafluoroborate	LiCAF	LiCaAlF_6
LAGB	low-angle grain boundary	LiSAF	lithium strontium aluminum fluoride
LAO	LiAlO_2	M	
LAP	L-arginine phosphate	M–S	melt–solid
LBIC	light-beam induced current	MAP	magnesium ammonium phosphate
LBIV	light-beam induced voltage	MASTRAPP	multizone adaptive scheme for transport and phase change processes
LBO	LiB_3O_5	MBE	molecular-beam epitaxy
LBO	LiBO_3	MBI	multiple-beam interferometry
LBS	laser-beam scanning	MC	multicrystalline
LBSM	laser-beam scanning microscope	MCD	magnetic circular dichroism
LBT	laser-beam tomography	MCT	HgCdTe
LCD	liquid-crystal display	MCZ	magnetic Czochralski
LD	laser diode	MD	misfit dislocation
LDT	laser-induced damage threshold	MD	molecular dynamics
LEC	liquid encapsulation Czochralski	ME	melt epitaxy
LED	light-emitting diode	ME	microelectronics
LEEBI	low-energy electron-beam irradiation	MEMS	microelectromechanical system
LEM	laser emission microanalysis	MESFET	metal-semiconductor field effect transistor
LEO	lateral epitaxial overgrowth	MHP	magnesium hydrogen phosphate-trihydrate
LES	large-eddy simulation	MI	morphological importance
LG	LiGaO_2	MIT	Massachusetts Institute of Technology
LGN	$\text{La}_3\text{Ga}_{5.5}\text{Nb}_{0.5}\text{O}_{14}$	ML	monolayer
LGO	LaGaO_3	MLEC	magnetic liquid-encapsulated Czochralski

MLEK	magnetically stabilized liquid-encapsulated Kyropoulos
MMIC	monolithic microwave integrated circuit
MNA	2-methyl-4-nitroaniline
MNSM	modified nonstationary model
MOCVD	metalorganic chemical vapor deposition
MOCVD	molecular chemical vapor deposition
MODFET	modulation-doped field-effect transistor
MOMBE	metalorganic MBE
MOS	metal–oxide–semiconductor
MOSFET	metal–oxide–semiconductor field-effect transistor
MOVPE	metalorganic vapor-phase epitaxy
mp	melting point
MPMS	mold-pushing melt-supplying
MQSSM	modified quasi-steady-state model
MQW	multiple quantum well
MR	melt replenishment
MRAM	magnetoresistive random-access memory
MRM	melt replenishment model
MSUM	monosodium urate monohydrate
MTDATA	metallurgical thermochemistry database
MTS	methyltrichlorosilane
MUX	multiplexor
MWIR	mid-wavelength infrared
MWRM	melt without replenishment model
MXRF	micro-area x-ray fluorescence

N

N	nucleus
N	nutrient
NASA	National Aeronautics and Space Administration
NBE	near-band-edge
NBE	near-bandgap emission
NCPM	noncritically phase matched
NCS	neighboring confinement structure
NGO	NdGaO ₃
NIF	National Ignition Facility
NIR	near-infrared
NIST	National Institute of Standards and Technology
NLO	nonlinear optic
NMR	nuclear magnetic resonance
NP	no-phonon
NPL	National Physical Laboratory
NREL	National Renewable Energy Laboratory
NS	Navier–Stokes
NSF	National Science Foundation
nSLN	nearly stoichiometric lithium niobate
NSLS	National Synchrotron Light Source
NSM	nonstationary model

NTRS	National Technology Roadmap for Semiconductors
NdBCO	NdBa ₂ Cu ₃ O _{7–x}

O

OCP	octacalcium phosphate
ODE	ordinary differential equation
ODLN	opposite domain LN
ODMR	optically detected magnetic resonance
OEIC	optoelectronic integrated circuit
OF	orientation flat
OFZ	optical floating zone
OLED	organic light-emitting diode
OMVPE	organometallic vapor-phase epitaxy
OPO	optical parametric oscillation
OSF	oxidation-induced stacking fault

P

PAMBE	photo-assisted MBE
PB	proportional band
PBC	periodic bond chain
pBN	pyrolytic boron nitride
PC	photoconductivity
PCAM	protein crystallization apparatus for microgravity
PCF	primary crystallization field
PCF	protein crystal growth facility
PCM	phase-contrast microscopy
PD	Peltier interface demarcation
PD	photodiode
PDE	partial differential equation
PDP	programmed data processor
PDS	periodic domain structure
PE	pendeo-epitaxy
PEBS	pulsed electron beam source
PEC	polyimide environmental cell
PECVD	plasma-enhanced chemical vapor deposition
PED	pulsed electron deposition
PEO	polyethylene oxide
PET	positron emission tomography
PID	proportional–integral–differential
PIN	positive intrinsic negative diode
PL	photoluminescence
PLD	pulsed laser deposition
PMNT	Pb(Mg, Nb) _{1–x} Ti _x O ₃
PPKTP	periodically poled KTP
PPLN	periodic poled LN
PPLN	periodic poling lithium niobate
ppy	polypyrrole
PR	photorefractive
PSD	position-sensitive detector
PSF	prismatic stacking fault

PSI	phase-shifting interferometry	RTV	room temperature vulcanizing
PSM	phase-shifting microscopy	R&D	research and development
PSP	pancreatic stone protein		
PSSM	pseudo-steady-state model	S	
PSZ	partly stabilized zirconium dioxide		
PT	pressure–temperature	S	stepped
PV	photovoltaic	SAD	selected area diffraction
PVA	polyvinyl alcohol	SAM	scanning Auger microprobe
PVD	physical vapor deposition	SAW	surface acoustical wave
PVE	photovoltaic efficiency	SBN	strontium barium niobate
PVT	physical vapor transport	SC	slow cooling
PWO	PbWO ₄	SCBG	slow-cooling bottom growth
PZNT	Pb(Zn, Nb) _{1–x} Ti _x O ₃	SCC	source-current-controlled
PZT	lead zirconium titanate	SCF	single-crystal fiber
		SCF	supercritical fluid technology
Q		SCN	succinonitrile
		SCW	supercritical water
QD	quantum dot	SD	screw dislocation
QDT	quantum dielectric theory	SE	spectroscopic ellipsometry
QE	quantum efficiency	SECeRTS	small environmental cell for real-time studies
QPM	quasi-phase-matched	SEG	selective epitaxial growth
QPMSHG	quasi-phase-matched second-harmonic generation	SEM	scanning electron microscope
QSSM	quasi-steady-state model	SEM	scanning electron microscopy
QW	quantum well	SEMATECH	Semiconductor Manufacturing Technology
QWIP	quantum-well infrared photodetector	SF	stacking fault
R		SFM	scanning force microscopy
		SGOI	SiGe-on-insulator
RAE	rotating analyzer ellipsometer	SH	second harmonic
RBM	rotatory Bridgman method	SHG	second-harmonic generation
RC	reverse current	SHM	submerged heater method
RCE	rotating compensator ellipsometer	SI	semi-insulating
RE	rare earth	SIA	Semiconductor Industry Association
RE	reference electrode	SIMS	secondary-ion mass spectrometry
REDG	recombination enhanced dislocation glide	SIOM	Shanghai Institute of Optics and Fine Mechanics
RELF	rare-earth lithium fluoride	SL	superlattice
RF	radiofrequency	SL-3	Spacelab-3
RGS	ribbon growth on substrate	SLI	solid–liquid interface
RHEED	reflection high-energy electron diffraction	SLN	stoichiometric LN
RI	refractive index	SM	skull melting
RIE	reactive ion etching	SMB	stacking mismatch boundary
RMS	root-mean-square	SMG	surfactant-mediated growth
RNA	ribonucleic acid	SMT	surface-mount technology
ROIC	readout integrated circuit	SNR	signal-to-noise ratio
RP	reduced pressure	SNT	sodium nonatitanate
RPI	Rensselaer Polytechnic Institute	SOI	silicon-on-insulator
RSM	reciprocal space map	SP	sputtering
RSS	resolved shear stress	sPC	scanning photocurrent
RT	room temperature	SPC	Scientific Production Company
RTA	RbTiOAsO ₄	SPC	statistical process control
RTA	rapid thermal annealing	SR	spreading resistance
RTCVD	rapid-thermal chemical vapor deposition	SRH	Shockley–Read–Hall
RTP	RbTiOPO ₄	SRL	strain-reducing layer
RTPL	room-temperature photoluminescence	SRS	stimulated Raman scattering
RTR	ribbon-to-ribbon		

SRXRD	spatially resolved XRD
SS	solution-stirring
SSL	solid-state laser
SSM	sublimation sandwich method
ST	synchrotron topography
STC	standard testing condition
STE	self-trapped exciton
STEM	scanning transmission electron microscopy
STM	scanning tunneling microscopy
STOS	sodium titanium oxide silicate
STP	stationary temperature profile
STS	space transportation system
SWBXT	synchrotron white beam x-ray topography
SWIR	short-wavelength IR
SXRT	synchrotron x-ray topography

T

TCE	trichloroethylene
TCNQ	tetracyanoquinodimethane
TCO	thin-film conducting oxide
TCP	tricalcium phosphate
TD	Tokyo Denpa
TD	threading dislocation
TDD	threading dislocation density
TDH	temperature-dependent Hall
TDMA	tridiagonal matrix algorithm
TED	threading edge dislocation
TEM	transmission electron microscopy
TFT-LCD	thin-film transistor liquid-crystal display
TGS	triglycine sulfate
TGT	temperature gradient technique
TGW	Thomson–Gibbs–Wulff
TGZM	temperature gradient zone melting
THM	traveling heater method
TMCZ	transverse magnetic-field-applied Czochralski
TMOS	tetramethoxysilane
TO	transverse optic
TPB	three-phase boundary
TPRE	twin-plane reentrant-edge effect
TPS	technique of pulling from shaper
TQM	total quality management
TRAPATT	trapped plasma avalanche-triggered transit
TRM	temperature-reduction method
TS	titanium silicate
TSC	thermally stimulated conductivity
TSD	threading screw dislocation
TSET	two shaping elements technique
TSFZ	traveling solvent floating zone
TSL	thermally stimulated luminescence
TSSG	top-seeded solution growth
TSSM	Tatarchenko steady-state model
TSZ	traveling solvent zone

TTV	total thickness variation
TV	television
TVM	three-vessel solution circulating method
TVTP	time-varying temperature profile
TWF	transmitted wavefront
TZM	titanium zirconium molybdenum
TZP	tetragonal phase

U

UC	universal compliant
UDLM	uniform-diffusion-layer model
UHPHT	ultrahigh-pressure high-temperature
UHV	ultrahigh-vacuum
ULSI	ultralarge-scale integrated circuit
UV	ultraviolet
UV-vis	ultraviolet–visible
UVB	ultraviolet B

V

VAS	void-assisted separation
VB	valence band
VB	vertical Bridgman
VBT	vertical Bridgman technique
VCA	virtual-crystal approximation
VCSEL	vertical-cavity surface-emitting laser
VCZ	vapor pressure controlled Czochralski
VDA	vapor diffusion apparatus
VGf	vertical gradient freeze
VLS	vapor–liquid–solid
VLSI	very large-scale integrated circuit
VLWIR	very long-wavelength infrared
VMCZ	vertical magnetic-field-applied Czochralski
VP	vapor phase
VPE	vapor-phase epitaxy
VST	variable shaping technique
VT	Verneuil technique
VTGT	vertical temperature gradient technique
VUV	vacuum ultraviolet

W

WBDF	weak-beam dark-field
WE	working electrode

X

XP	x-ray photoemission
XPS	x-ray photoelectron spectroscopy
XPS	x-ray photoemission spectroscopy
XRD	x-ray diffraction
XRPD	x-ray powder diffraction
XRT	x-ray topography

Y		YPS	(Y ₂)Si ₂ O ₇
		YSO	Y ₂ SiO ₅
		Z	
YAB	YAl ₃ (BO ₃) ₄	ZA	Al ₂ O ₃ -ZrO ₂ (Y ₂ O ₃)
YAG	yttrium aluminum garnet	ZLP	zero-loss peak
YAP	yttrium aluminum perovskite	ZM	zone-melting
YBCO	YBa ₂ Cu ₃ O _{7-x}	ZNT	ZN-Technologies
YIG	yttrium iron garnet	ZOLZ	zero-order Laue zone
YL	yellow luminescence		
YLF	LiYF ₄		
YOF	yttrium oxyfluoride		

Part A Fundamentals

Part A Fundamentals of Crystal Growth and Defect Formation

1 Crystal Growth Techniques and Characterization: An Overview

Govindhan Dhanaraj, Nashua, USA
Kullaiah Byrappa, Mysore, India
Vishwanath (Vish) Prasad, Denton, USA
Michael Dudley, Stony Brook, USA

2 Nucleation at Surfaces

Ivan V. Markov, Sofia, Bulgaria

3 Morphology of Crystals Grown from Solutions

Francesco Abbona, Torino, Italy
Dino Aquilano, Torino, Italy

4 Generation and Propagation of Defects During Crystal Growth

Helmut Klapper, Aachen, Germany

5 Single Crystals Grown Under Unconstrained Conditions

Ichiro Sunagawa, Tokyo, Japan

6 Defect Formation During Crystal Growth from the Melt

Peter Rudolph, Berlin, Germany

1. Crystal Growth Techniques and Characterization: An Overview

Govindhan Dhanaraj, Kullaiah Byrappa, Vishwanath (Vish) Prasad, Michael Dudley

A brief overview of crystal growth techniques and crystal analysis and characterization methods is presented here. This is a prelude to the details in subsequent chapters on fundamentals of growth phenomena, details of growth processes, types of defects, mechanisms of defect formation and distribution, and modeling and characterization tools that are being employed to study as-grown crystals and bring about process improvements for better-quality and large-size crystals.

1.1	Historical Developments	3	1.2	Theories of Crystal Growth	4
			1.2.1	Surface Energy Theory.....	5
			1.2.2	Diffusion Theory.....	5
			1.2.3	Adsorption Layer Theory.....	6

1.1 Historical Developments

Crystals are the unacknowledged pillars of the world of modern technology. They have attracted human civilization from prehistoric times owing to their beauty and rarity, but their large-scale applications for devices have been realized only in the last six decades. For a long time, crystal growth has been one of the most fascinating areas of research. Although systematic understanding of the subject of crystal growth began during the last quarter of the 19th century with Gibbs' phase equilibrium concept based on a thermodynamical treatment, man practiced crystal growth and or crystallization processes as early as 1500 BC in the form of salt and sugar crystallization. Thus, crystal growth can be treated as an ancient scientific activity. However, the scientific approach to the field of crystal growth started in 1611 when Kepler correlated crystal morphology and structure, followed by Nicolous Steno, who explained the origin of a variety of external forms. Since then crystal growth has evolved steadily to attain its present status. Several theories were proposed from the 1920s onwards. The current impetus in crys-

tal growth started during World War II. Prior to that, applications of crystals and crystal growth technology did not catch the attention of technologists. The growth of small or fine crystals in the early days, which involved uncontrolled or poorly controlled crystal growth parameters without much sophistication in instrumentation or crystal growth equipment, slowly led to the growth of large bulk crystals during World War II. With advancement in instrumentation technology, the attention of crystal growers focused on the quality of the grown crystals and understanding of their formation. Also, tailoring of crystal shape or morphology, size, and properties plays a key role in crystal growth science. In this context it is appropriate to mention nanocrystals, which exhibit desirable physicochemical characteristics. Similarly, the growth of thin films has emerged as a fascinating technology. Further crystal growth research is being carried out in microgravity or space conditions. There are various methods of evaluating the quality of grown crystals. Thus the growth of crystals with tailored physics and chemistry, characterization of crystals

with more advanced instrumentation, and their conversion into useful devices play vital roles in science and technology [1.1,2].

Crystal growth is a highly interdisciplinary subject that demands the collaboration of physicists, chemists, biologists, engineers, crystallographers, process engineers, materials scientists, and materials engineers. The significance of the beauty and rarity of crystals is now well knitted with their symmetry, molecular structure, and purity, and the physicochemical environment of their formation. These characteristics endow crystals with unique physical and chemical properties, which have transformed electronic industries for the benefit of human society. Prior to commercial growth or production of crystals, man depended only on the availability of natural crystals for both jewelry and devices. Today the list of uses of artificially grown crystals is growing exponentially for a variety of applications, such as electronics, electrooptics, crystal bubble memories, spintronics, magnetic devices, optics, nonlinear devices, oscillators, polarizers, transducers, radiation detectors, lasers, etc. Besides inorganic crystal growth, the world of organic, semiorganic, biological crystal growth is expanding greatly to make crystal growth activity more cost-effective. Today, the quality, purity, and defect-free nature of crystals is a prerequisite for their technological application. A reader can get useful information

on the history of crystal growth from the works of Scheel [1.3,4].

Crystal growth is basically a process of arranging atoms, ions, molecules or molecular assemblies into regular three-dimensional periodic arrays. However, real crystals are never perfect, mainly due to the presence of different kinds of local disorder and long-range imperfections such as dislocations. Moreover, they are often polycrystalline in nature. Hence, the ultimate aim of a crystal grower is to produce perfect single crystals of desired shape and size, and to characterize them in order to understand their purity and quality and perfection for end users. Accordingly, crystal growth techniques and characterization tools have advanced greatly in recent years. This has facilitated the growth and characterization of a large variety of technologically important single crystals. Crystal growth can be treated as an important branch of materials science leading to the formation of technologically important materials of different sizes. Hence, it covers crystals from bulk to small and even to fine, ultrafine, and nanoscale sizes. In this respect, crystal growth has a close relationship with crystal engineering, and also polyscale crystal growth is relevant. This concept becomes even more relevant with progress achieved in nanotechnology, wherein the size effect explains changes in the physical properties of crystalline materials with size.

1.2 Theories of Crystal Growth

Growth of single crystals can be regarded as a phase transformation into the solid state from the solid, liquid or vapor state. Solid–solid phase transformations are rarely employed to grow single crystals, except for certain metals and metal alloys, whereas liquid to solid and vapor to solid transformations are most important in crystal growth and have resulted in a great variety of experimental techniques. When a crystal is in dynamic equilibrium with its mother phase, the free energy is at a minimum and no growth can occur. This equilibrium has to be disturbed suitably for growth to occur. This may be done by an appropriate change in temperature, pressure, pH, chemical potential, electrochemical potential, strain, etc. The three basic steps involved in the formation of a crystal from an initially disordered phase are:

1. Achievement of supersaturation or supercooling
2. Nucleation

3. Growth of the nuclei into single crystals of distinct phases

The driving force for crystallization actually derives from supersaturation, supercooling of liquid or gas phase with respect to the component whose growth is required. Therefore steady-state supersaturation/supercooling needs to be maintained during crystal growth to obtain higher-quality results. Nucleation or crystallization centers are an important feature of crystal growth. Nucleation may occur either spontaneously due to the conditions prevailing in the parent phase or it may be induced artificially. Therefore, the study of nucleation forms an integral part of crystal growth process. Several theories to explain nucleation have been proposed from time to time. Perhaps Gibbs was the first to comprehend that the formation of small embryonic clusters of some critical size is a prerequisite for the development of a macroscopic crystal. The

Gibbs–Thomson equation is fundamental for nucleation events [1.5], expressed for a cluster inside a supercooled phase under equilibrium conditions inside a supersaturated/supercooled phase as

$$k_B T \ln \left(\frac{p}{p^*} \right) = \frac{2\sigma V}{r}, \quad (1.1)$$

where r is the radius of the cluster formed inside a vapor at temperature T , k_B is the Boltzmann constant, p is the vapor pressure outside the cluster, p^* is the saturated vapor pressure over a plane liquid surface, σ is the surface energy per unit area, and V is the volume of the growth units.

For nucleation from solution,

$$k_B T \ln \left(\frac{c}{c^*} \right) = \frac{2\sigma V}{r}. \quad (1.2)$$

Here, c is the actual concentration and c^* is the concentration of the solution with a crystal of infinite radius. The condition for nucleation from the melt is

$$\Delta H_m \left(\frac{T_m - T_r}{T_m} \right) = \frac{2\sigma V}{r}. \quad (1.3)$$

Here, T_r is the melting point of a crystal of radius r and T_m is the melting point of a large crystal. ΔH_m is the latent heat of fusion per molecule.

The Gibbs–Thomson equation, which gives the free energy change per unit volume for solution growth, is given by

$$\Delta G_v = \frac{2\sigma}{r} = -k_B T \ln \left(\frac{c}{c^*} \right) = -\frac{k_B}{V} \ln S, \quad (1.4)$$

where S is the degree of supersaturation and V is the molecular volume.

There are several theories to explain crystal growth, involving the mechanism and the rate of growth of crystals. The important crystal growth theories are the surface energy theory, diffusion theory, adsorption layer theory, and screw dislocation theory. Gibbs proposed the first theory of crystal growth, in which he assumed growth of crystals to be analogous to the growth of a water droplet from mist. Later *Kossel* and others explained the role of step and kink sites on the growth surface in promoting the growth process [1.6].

1.2.1 Surface Energy Theory

The surface energy theory is based on the thermodynamic treatment of equilibrium states put forward by Gibbs. He pointed out that the growing surface would assume that shape for which the surface energy is lowest. Many researchers later applied this idea. *Curie* [1.7]

worked out the shapes and morphologies of crystals in equilibrium with solution or vapor. Later, *Wulff* [1.8] deduced expressions for the growth rate at different faces and the surface free energies. According to him, the equilibrium is such that excess surface free energy $\sigma_{hkl} dA_{hkl}$ is minimum for crystal with its $\{hkl\}$ faces exposed. The value of σ_{hkl} determines the shape of a small crystal; for example, if σ is isotropic, the form of the crystal is spherical, provided the effect of gravity is negligible. *Marc* and *Ritzel* [1.9] considered the effect of surface tension and solution pressure (solubility) on the growth rate. In their opinion, different faces have different values of solubility. When the difference in solubility is small, growth is mainly under the influence of surface energy, and the change in the surface of one form takes place at the expense of the other. *Bravais* [1.10] proposed that the velocities of growth of the different faces of a crystal depend on the reticular density.

1.2.2 Diffusion Theory

The diffusion theory proposed by *Nernst* [1.11], *Noyes*, and *Whitney* [1.12] is based on the following two basic assumptions:

1. There is a concentration gradient in the neighborhood of the growing surface;
2. Crystal growth is the reverse process of dissolution.

Consequently, the amount of solute that will get deposited on a crystal growing in a supersaturated solution is given by

$$\frac{dm}{dt} = \left(\frac{D}{\delta} \right) A(c - c_0), \quad (1.5)$$

where dm is the mass of solute deposited in a small time interval dt over an area A of the crystal surface, D is the diffusion coefficient of the solute, c and c_0 are the actual and equilibrium concentrations of the solute, and δ is the thickness of the torpid layer adjacent to the solid surface.

The importance of surface discontinuities in providing nucleation sites during crystal growth was the main consideration of *Kossel* [1.6], *Stranski* [1.13], and *Volmer* [1.14]. *Volmer* suggested a growth mechanism by assuming the existence of an adsorbed layer of atoms or molecules of the growth units on crystal faces. Later, *Brandes* [1.15], *Stranski*, and *Kossel* modified this concept. *Volmer's* theory was based on thermodynamical reasoning. The units reaching a crystal face are not immediately attached to the lattice but migrate over the

Fig. 1.1a,b Screw dislocation in a crystal (a); edge dislocation (b)

crystal face to find a suitable site for attachment. They form a loosely adsorbed layer at the interface, and soon a dynamic equilibrium is established between the layer and the bulk solution.

1.2.3 Adsorption Layer Theory

Kossel viewed crystal growth based on atomistic considerations. He assumed that crystal is in equilibrium with its solution when it is just saturated. Also, the attachment energy unit on growing surface is a simple function of distance only. The attachment energy is due to van der Waals forces if the crystal is homopolar, while it is due to electrostatic forces if the crystal is heteropolar (ionic). A growth unit arriving at a crystal surface finds attachment sites such as terraces, ledges, and kinks. The attachment energy of a growth unit can be considered to be the resultant of three mutually perpendicular components. The binding energy or attachment energy of an atom is maximum when it is incorporated into a kink site in a surface ledge, whilst at any point on the ledge it is greater than that for an atom attached to the flat surface (terrace). Hence, a growth unit reaching a crystal surface is not integrated into the lattice immediately. Instead

it migrates to a step and moves along it to a kink site, where it is finally incorporated. Based on this consideration of attachment, Kossel was able to determine the most favorable face for growth. According to the Kossel model, growth of a crystal is a discrete process and not continuous. Also, a new layer on a preferably flat face of a homopolar crystal will start growing from the interior of the face. For heteropolar crystals, the corners are the most favorable for growth, while mid-face is least favored. According to Stranski, the critical quantity that determines the growth process is the work necessary to detach a growth unit from its position on the crystal surface. Growth units with the greatest detachment energy are most favored for growth, and vice versa. The greatest attraction of atoms to the corners of ionic and metallic crystals often leads to more rapid growth along these directions, with the result that the crystal grows with many branches called dendrites radiating from a common core.

1.2.4 Screw Dislocation Theory

However, the Kossel, Stranski, and Volmer theory could not explain the moderately high growth rates observed in many cases at relatively low supersaturation, far below those needed to induce surface nucleation. *Frank* [1.16] proposed that a screw dislocation emerging at a point on the crystal surface could act as a continuous source of steps (surface ledges) which can propagate across the surface of the crystal and promote crystal growth. Growth takes place by rotation of the steps around the dislocation point (Fig. 1.1). *Burton et al.* [1.17] proposed the famous screw dislocation theory based on the relative supersaturation as the Burton–Cabrera–Frank (BCF) model determining the absolute value of growth rate depending upon the concentration. Frank's model could explain the experimental observations on the growth rate and spiral pattern mechanism.

1.3 Crystal Growth Techniques

Crystal growth is a heterogeneous or homogeneous chemical process involving solid or liquid or gas, whether individually or together, to form a homogeneous solid substance having three-dimensional atomic arrangement. Various techniques have been employed, depending upon the chemical process involved. All

crystal growth processes can be broadly classified according to the scheme presented in Table 1.1. The subject of crystal growth has therefore developed as an interdisciplinary subject covering various branches of science, and it is extremely difficult to discuss the entire subject in this overview chapter. However, the

Table 1.1 Classification of crystal growth processes [1.18]

1. Solid–Solid	Solid	\xrightarrow{T}	Solid Devitrification Strain annealing Polymorphic phase change Precipitation from solid solution
2. Liquid–Solid			
i) Melt growth	Molten material	$\xrightarrow{\text{Dec. } T}$	Crystal Bridgman–Stockbarger Kyropoulos Czochralski Zoning Verneuil
ii) Flux growth	Solid(s) + Flux agent(s)	$\xrightarrow{\text{Dec. } T}$	Crystal(s)

v) Gel growth	Solution + Gel medium	$\xrightarrow{\text{Low } T}$	Crystal Reaction Complex decomplex Chemical reduction Solubility reduction Counter-flow diffusion
	Solution	\longrightarrow	Crystal(s) + products
3. Gas–Solid	Vapor(s)	\longrightarrow	Solid Sublimation–condensation Sputtering Epitaxial processes Ion-implantation

present Handbook covers most important techniques adopted in modern crystal growth through the chapters authored by world authorities in their respective fields.

1.3.1 Solid Growth

The solid-state growth technique is basically controlled by atomic diffusion, which is usually very slow ex-

cept in the case of fast ionic conductors or superionic conductors. The commonly used solid-state growth techniques are annealing or sintering, strain annealing, heat treatment, deformation growth, polymorphic phase transitions, quenching, etc., and most of these are popularly used in metallurgical processes for tailoring material properties. In fact, gel growth is also considered as solid growth by some researchers. Solid growth is not covered in this Handbook.

1.3.2 Solution Growth

This is one of the oldest and most widely used crystal growth techniques compared with vapor-phase melt growth. Solution growth is used not only for growth of technologically important crystals but also for a variety of crystalline products for daily life such as the growth of foods, medicines, fertilizers, pesticides, dye stuffs, etc. Most crystallization processes of ionic salts are conducted in aqueous solutions or in some cases in solvents which are a mixture of miscible and organic solvents. Solution growth is used for substances that melt incongruently, decompose below the melting point, or have several high-temperature polymorphic modifications, and is also often efficient in the absence of such restrictions. The important advantage of solution growth is the control that it provides over the growth temperature, control of viscosity, simplicity of equipment, and the high degree of crystal perfection since the crystals grow at temperatures well below their melting point. We can divide solution growth into three types depending upon the temperature, the nature of the solvent, solute, and the pressure: low-temperature aqueous solution growth, superheated aqueous solution growth, and high-temperature solution growth. Aqueous solution growth has produced the largest crystals known to mankind, such as potassium dihydrogen phosphate (KDP), deuterated potassium dihydrogen phosphate (DKDP), etc. produced at the Lawrence Livermore Laboratory, USA.

For successful growth of a crystal from solution, it is essential to understand certain basic properties (physicochemical features) of the solution. The behavior of water with temperature and pressure; the critical, subcritical, and supercritical conditions; its structure, the variation in pH; viscosity; density; conductivity; dielectric constant; and coefficient of expansion are critical for successful crystal growth. Recently, a rational approach to the growth of a given crystal was carried out in order to: compute the thermodynamic equilibrium as a function of the processing variables, generate equilibrium (yield) diagrams to map the processing variable space for the phases of interest, design experiments to test and validate the computed diagrams, and utilize the results for mass production [1.19]. The change in ionic strength of the solution during crystal growth results in formation of defects, and variation in the crystal habit and even the phases, and therefore has to be maintained constant, often with the help of swamping-electrolyte solutions. Similarly, chelating agents are frequently used to sequester ions and form respective complexes,

which are later thermodynamically broken to release their cations very slowly into the solution, which helps in controlling the growth rate and crystal habit.

In the last decade crystal growth from solution under microgravity conditions has been studied extensively to grow a wide variety of crystals such as zeolites, compound semiconductors (InP, GaAs, GaP, AlP, etc.), triglycine sulfate, etc.

Crystal Growth from Low-Temperature Aqueous Solutions

The greatest advantages of crystal growth from low-temperature aqueous solutions are the proximity to ambient temperature, which helps to retain a high degree of control over the growth conditions, especially with reference to thermal shocks, and reduction of both equilibrium and nonequilibrium defects to a minimum (even close to zero). Solution growth can be classified into several groups according to the method by which supersaturation is achieved:

1. Crystallization by changing the solution temperature
2. Crystallization by changing the composition of the solution (solvent evaporation)
3. Crystallization by chemical reaction

Crystal Growth from Superheated Aqueous Solutions

This method is commonly known as the hydrothermal method and is highly suitable for crystal growth of compounds with very low solubility and phase transitions. When nonaqueous solvents are used in the system, it is called the solvothermal method. The largest known single crystal formed in nature (beryl crystal of > 1000 kg) is of hydrothermal origin, and similarly some of the largest quantities of single crystals produced in one experimental run (quartz single crystals of > 1000 kg) are based on the hydrothermal technique. The term “hydrothermal” refers to any heterogeneous (usually for bulk crystal growth) or homogeneous (for fine to nanocrystals) chemical reaction in the presence of aqueous solvents or mineralizers under high-pressure and high-temperature conditions to dissolve and recrystallize (recover) materials that are relatively insoluble under ordinary conditions [1.20]. The last decade has witnessed growing popularity of this technique, and a large variety of crystals and crystalline materials starting from native elements to the most complex coordinated compounds such as rare-earth silicates, germinates, phosphates, tungstates, etc. have been obtained. Also,

the method is becoming very popular among organic chemists dealing with synthesis of life-forming compounds and problems related to the origin of life. The method is discussed in great detail in Chap. 18.

Crystal Growth from High-Temperature Solutions

This is popularly known as flux growth and gained its importance for growing single crystals of a wide range of materials, especially complex multicomponent systems. In fact, this was one of the earliest methods employed for growing technologically important crystals, for example, single crystals of corundum at the end of the 19th century. The main advantage of this method is that crystals are grown below their melting temperature. If the material melts incongruently, i.e., decomposes before melting or exhibits a phase transition below the melting point or has very high vapor pressure at the melting point, one has indeed to look for growth temperatures lower than these phase transitions. The method is highly versatile for growth of single crystals as well as layers on single-crystal substrates (so-called liquid-phase epitaxy, **LPE**). The main disadvantages are that the growth rates are smaller than for melt growth or rapid aqueous solution growth, and the unavoidable presence of flux ions as impurities in the final crystals. Some of the important properties to be considered for successful flux growth of crystals are stability and solubility of the crystal to be grown, low melting point and lower vapor pressure of the flux, the lower viscosity of the melt (which should not attack the crucible), and also ease of separation [1.4,21]. The most commonly used fluxes are the basic oxides or fluorides: PbO, PbF₂, BaO, BaF, Bi₂O₃, Li₂O, Na₂O, K₂O, KF, B₂O₃, P₂O₅, V₂O₅, MoO₃, and in most cases a mixture consisting of two or three of them. The prime advantage of this method is that growth can be carried out either through spontaneous nucleation or crystallization on a seed. Supersaturation can be achieved through slow cooling, flux evaporation, and vertical temperature gradient transport methods. Also, during the growth, one can introduce rotation of the seed or crucible, or pulling of the seed, and so on. Accordingly, several versions of flux growth have been developed: slow cooling (**SC**), slow cooling bottom growth (**SCBG**), top-seeded solution growth (**TSSG**), the top-seeded vertical temperature gradient technique (**VTGT**), bottom growth with a nutrient, growth by traveling solvent zone (**TSZ**), flux evaporation, **LPE**, and so on.

The flux method has been popularly used especially for the growth of a large variety of garnets, and recently

for a wide range of laser crystals such as rare-earth borates, potassium titanyl phosphates, and so on. The reader can get valuable information from several interesting reviews on flux growth [1.22–24].

1.3.3 Crystal Growth from Melt

Melt growth of crystals is undoubtedly the most popular method of growing large single crystals at relatively high growth rates. In fact, more than half of technological crystals are currently obtained by this technique. The method has been popularly used for growth of elemental semiconductors and metals, oxides, halides, chalcogenides, etc. Melt growth requires that the material melts without decomposition, has no polymorphic transitions, and exhibits low chemical activity (or manageable vapor pressure at its melting point). The thermal decomposition of a substance and also chemical reactions in the melt can disturb the stoichiometry of the crystal and promote formation of physical or chemical defects. Similarly, the interaction between the melt and crucible, or the presence of a third component derived from the crystallization atmosphere, can affect melt growth. Usually, an oxygen-containing atmosphere is used for oxides, a fluorine-containing atmosphere for fluorides, a sulfur-containing atmosphere for sulfides, and so on. In melt growth, crystallization can be carried out in a vacuum, in a neutral atmosphere (helium, argon, nitrogen), or in a reducing atmosphere (air, oxygen). In a large melt volume, convective flows caused by the temperature gradient within the melt lead to several physical and chemical defects. In a small melt volume, transport is affected by diffusion.

Selection of a particular melt growth technique is done on the basis of the physical and chemical characteristics of the crystal to be grown. Metal single crystals with melting point < 1800 °C are grown by Stockbarger method, and those with melting point > 1800 °C by zone melting. Semiconducting crystals are grown chiefly by Czochralski method, and by zone melting. Single crystals of dielectrics with melting point < 1800 °C are usually grown by the Stockbarger or Czochralski methods, while higher-melting materials are produced by flame fusion (Verneuil method). If the physicochemical processes involved in crystallization are taken into account, it is possible to establish optimum growth conditions.

One of the earliest melt techniques used to grow large quantity of high-melting materials was the Verneuil method (flame fusion technique), first described by *Verneuil* in 1902 [1.25]. This marks the

beginning of commercial production of large quantities of high-melting crystals, which were essentially used as gems or for various mechanical applications. Today, the technique is popular for growth of a variety of high-quality crystals for laser devices and precision instruments, as well as substrates. The essential features are a seed crystal, the top of which is molten and is fed with molten drops of source material, usually as a powder through a flame or plasma. Following this, the Czochralski method, developed in 1917 and later modified by several researchers, became the most popular technique to grow large-size single crystals which were impossible to obtain by any other techniques in such large quantity. This technique has several advantages over the other related melt-growth technique, viz. the Kyropoulos method, which involves a gradual reduction in the melt temperature. In the Czochralski technique the melt temperature is kept constant and the crystal is slowly pulled out of the melt as it grows. This provides a virtually constant growth rate for the crystal. Several versions of Czochralski crystal pullers are commercially available. A large variety of semiconductor crystals such as Si, Ge, and several III–V compounds are being commercially produced using this technique. Besides, several other crystals of oxides, spinel, garnets, niobates, tantalates, and rare-earth gallates have been obtained by this method. The reader can find more valuable information on this method from the works of *Hurle and Cockayne* [1.26].

There are several other popularly used melt growth techniques that are feasible for commercial production of various crystals. Amongst them, the Bridgman–Stockbarger, zone melting, and floating zone methods are the most popular. The Bridgman technique is characterized by the relative translation of the crucible containing the melt to the axial temperature gradient in a vertical furnace. The Stockbarger method is a more sophisticated modification of the Bridgman method. There is a high-temperature zone, an adiabatic loss zone, and a low-temperature zone. The upper and lower temperature zones are generally independently controlled, and the loss zone is either unheated or poorly insulated.

1.3.4 Vapor-Phase Growth

Vapor-phase growth is particularly employed in mass production of crystals for electronic devices because of its proven low cost and high throughput, in addition to its capability to produce advanced epitaxial structures. The technique is especially suitable for growth of

semiconductors, despite the rather complex chemistry of the vapor-phase process. The fundamental reason for their success is the ease of dealing with low- and high-vapor-pressure elements. This is achieved by using specific chemical precursors in the form of vapor containing the desired elements. These precursors are introduced into the reactor by a suitable carrier gas and normally mix shortly before reaching the substrate, giving rise to the nutrient phase of the crystal growth process. The release of the elements necessary for construction of the crystalline layer may occur at the solid–gas interface or directly in the gas phase, depending on the type of precursors and on the thermodynamic conditions.

The advantage of vapor growth technique is that crystals tend to have a low concentration of point defects and low dislocation densities compared with crystals grown from the melt, as the temperatures employed are usually considerably lower than the melting temperature. Moreover, if the material undergoes a phase transformation or melts incongruently, vapor growth may be the only choice for the growth of single crystals. Although the method was initially used to grow bulk crystals, with the enormous importance of thin films in electronic and metallurgical applications, vapor growth is now widely used to grow thin films, epitaxial layers, and substrates in the field of semiconductor technology [1.27, 28].

Vapor-phase growth primarily involves three stages: vaporization, transport, and deposition. The vapor is formed by heating a solid or liquid to high temperatures. Transportation of vapor may occur through vacuum, driven by the kinetic energy of vaporization. Deposition of the vapor may occur by condensation or chemical reaction.

Various techniques exist in vapor-phase growth, differentiated by the nature of the source material and the means and mechanism by which it is transported to the growing crystal surface. Conceptually, the simplest technique is that of sublimation, where the source material is placed at one end of a sealed tube and heated so that it sublimates and is then transported to the cooler region of the tube, where it crystallizes.

Among vapor-phase growth techniques, vapor-phase epitaxy is the most popularly used, especially for the growth of p- and n-type semiconductor whose dimers and monomers are difficult to achieve by other methods (e.g., physical evaporation) or too stable to be reduced to the necessary atomic form. Furthermore, there are different variants such as metalorganic vapor-phase epitaxy (MOVPE), plasma-assisted mo-

Table 1.2 Main application fields of vapor-phase epitaxy techniques and the relevant classes of materials

Growth technique	Devices and semiconductor family			
	Si, Ge	II–VI	III–V	III–nitrides
Hydride VPE	SiGe alloys		LEDs and photodetectors (GaP, InGaP, GaAsP)	GaN thick layers
Chloride VPE MOVPE	Bipolar transistors, MOS	IR sensors (HgCdTe), LEDs and lasers (ZnCdSe, ZnSSe)	Solar cells (GaAs, AlGaAs, InGaP), transistors (AlGaAs, InGaAs), LEDs (AlGaAs), TC and CD lasers (InGaPAs, AlGaAs), photodetectors, LEDs and lasers (InGaPAs)	LEDs and lasers (GaN, InGaN, GaAlN)

molecular beam epitaxy (MBE), etc. to suit the growth of particular compounds. Table 1.2 summarizes the main

application fields of the VPE techniques and the relevant classes of materials [1.29].

1.4 Crystal Defects and Characterization

Characterization of crystals has become an integral part of crystal growth and process development. Crystal defects and their distribution together with composition and elemental purity determine most of their properties such as mechanical strength, electrical conductivity, photoconductivity luminescence, and optical absorption, and these properties influence their performance in applications. Therefore, investigating the origin, concentration, and distribution of imperfections in crystals is critical to controlling them and thereby the crystal properties influenced by these imperfections.

1.4.1 Defects in Crystals

Imperfections or defects can be broadly classified based on their dimensionality.

Point Defects

These zero-dimensional defects are vacancies, interstitials, and impurity atoms deliberately added to control the conductivity of the semiconductor, and impurities that are unintentionally incorporated as contaminants during material growth and processing. Electronic defects such as holes and electrons also constitute point defects. In compounds, point defects form disorders such as Frenkel, Schottky, and antistructure disorders.

Line Defects

Line defects consist of purely geometrical faults called dislocations. The concept of dislocations arose from

the crystallographic nature of plastic flow in crystalline materials. A dislocation is characterized by its line direction and Burgers vector \mathbf{b} , which is, as a rule, one of the shortest lattice translations. Dislocation lines may be straight or follow irregular curves or closed loops. Dislocations whose line segments are parallel to \mathbf{b} are called screw dislocations. Edge dislocations have their line segments perpendicular to the \mathbf{b} direction. In mixed dislocations, the line direction is inclined to \mathbf{b} and hence they have both screw and edge components.

Planar Defects

Planar defects include high- and low-angle boundaries, growth striations, growth-sector boundaries, twin boundaries, stacking faults, and antiphase boundaries. Growth striations are lattice perturbations that arise from local variations of the dopant/impurity concentration created by fluctuations in the growth conditions. Stacking faults are formed when there are errors in the normal stacking arrangement of the lattice planes in the crystal structure. These could be caused by plastic deformation or agglomeration of point defects. High- and low-angle boundaries consist of arrays of dislocations, and they separate regions of different orientations. In crystal growth, high-angle boundaries separate grains that have been nucleated independently, and hence misorientations are generally large. Low-angle grain boundaries are formed during cool down by stress-induced glide and climb of dislocations, leading to these energetically favorable configurations. Misorientations

in this case usually do not exceed more than 1° . Twin boundaries are planar defects that separate regions of the crystal whose orientations are related to each other in a definite, symmetrical way.

Volume Defects

Precipitates, inclusions, and voids or bubbles are volume defects, and these are formed when gases dissolved in the melt precipitate out after solidification. For example, in microgravity growth, the absence of buoyancy precludes degassing of the melt, resulting in the formation of voids. While undissolved foreign particles are generally classified as inclusions, a second type of inclusion is formed during growth from nonstoichiometric melt. Compound semiconductors generally sublime incongruently, thereby causing a slight excess of one of the components in a stoichiometric melt. On solidification, the excess component forms inclusions.

1.4.2 Observation of Crystal Defects

Techniques for observing dislocations and their complex structures have been described in detail by *Verma* [1.30] and *Amelincks* [1.31]. The commonly used techniques come under the categories:

1. Optical methods
2. X-ray methods
3. Preferential etching
4. Microscopy techniques
5. Other techniques

All these methods provide almost direct observation of defects. Their merit is limited by the resolution achievable and their versatility. Choice of a suitable technique will depend on several factors, such as:

1. The shape and size of the crystal under investigation
2. Cleaving, cutting, and polishing possibilities

Optical Methods

A common inspection method for the as-grown optical crystal boule is detailed observation by illuminating the boule using high-intensity white light or a laser beam. Probably, this is the first technique to be applied to assess the quality of as-grown crystal and can reveal bubbles, cavities, growth bands, and seed interfaces which depend on the growth parameters.

The conoscope is a simple optical tool for investigating optical inhomogeneity in very small crystals to

large-size boules. Conoscopic patterns are characteristic for every main crystallographic orientation, and this feature is also frequently used for orienting crystals [1.32]. This method shows the overall quality of the crystal. If the whole crystal has low dislocation density without any grain boundaries and block structures, a nice symmetrical circular pattern of dark and bright fringes with four segments and a cross at the center is observed. Figure 1.2a shows the conoscopic pattern of a sapphire ingot with dislocation density 10^2 – 10^3 /cm² and without any low-angle grain boundaries. Figure 1.2b shows the pattern for a sapphire ingot of the same size but with a dislocation density of the order of 10^3 – 10^4 /cm² and a few low-angle grain boundaries. The presence of a few grain boundaries alters the birefringence and distorts the fringes. The fringe thickness and spacing depend on the length of the crystal along the direction of inspection. Even though this technique does not reveal the dislocation density very precisely, it can reveal the presence of grain boundaries and higher-order, complex defects. The crystals are normally sliced perpendicular to the *c*-axis, polished, and inspected under a polarizer and analyzer. As-cut surfaces without polishing can also be observed with the application of suitable refractive-index-matched fluid. In general, this technique can reveal the misorientations, grain boundaries, block structures, and also the stress levels. Conoscopy can be used under a polarizing microscope to study thinner samples. A custom-made polarizer and analyzer with rotation features for the analyzer and sample support can be used to study large crystal boules. Alternatively, conoscopic fringes can be projected onto a screen using a laser beam, polarizer and analyzer, and beam diffuser. These fringes are more influenced by the birefringence inhomogeneity induced by defect structures than by variation in the thickness distribution of the boule itself.

X-Ray Methods

X-ray methods can be classified into:

1. High-resolution x-ray diffraction
2. X-ray topography
3. Synchrotron x-ray topography

High-Resolution X-Ray Diffraction. Diffraction for a given plane and wavelength takes place over a finite angular range about the exact Bragg condition, known as the rocking-curve width [1.33]. In x-ray diffractometry, the intensity of the diffracted beam and the angle in the vicinity of a Bragg peak are measured and repre-

sented as a full-width at half-maxima (FWHM) rocking curve. The double-axis rocking curve is obtained by scanning the specimen in small steps through the exact Bragg condition and recording the diffracted intensity. The peak width of a rocking curve can be affected by tilts and dilations in the sample, and by curvature. Tilts are regions in the sample where grains or subgrains are tilted with respect to each other, although the lattice parameter is the same in each region. Dilations are regions where the lattice planes are still parallel but the spacing is slightly different due to strain. Changes in lattice parameter also occur in alloyed crystals with nonhomogeneous composition distribution. The experimentally obtained rocking-curve width (FWHM) value is a measure of the crystalline quality of the sample, and it can be compared with a theoretically calculated value. It is possible to obtain a rocking-curve width less than 10 arcsec for a good crystalline sample. Additional information that can be obtained from double-axis rocking curves are substrate–epilayer mismatch, epilayer composition, substrate offcut and/or layer tilt, and layer thickness.

A limitation of double-axis diffraction is that it cannot distinguish between tilts and dilations. In triple-axis diffraction, a third axis is introduced in the form of an analyzer crystal, and tilts and strain can be separated; the rocking-curve width is still narrow. Double-axis rocking curve analysis is sufficient for studying substrates and epitaxial films. Triple-axis x-ray diffraction is used for obtaining finer details of the defect structure of the sample.

X-Ray Topography. Localized variations in intensity within any individual diffracted spot arise from structural nonuniformity in the lattice planes causing the spot, and this forms the basis for the x-ray topographic technique. This topographic contrast arises from differences in the intensity of the diffracted beam as a function of position inside the crystal. The difference between the intensities diffracted from one region of the crystal which diffracts kinematically to another which diffracts dynamically is one of the ways that dislocations can be rendered visible in topography [1.34].

Even though the first topographic image of a single crystal was recorded as early as 1931 [1.35], the real potential of the technique was understood only in 1958 when Lang [1.36] demonstrated imaging of individual dislocations in a silicon crystal. In general, there are three main types of x-ray topographic geometries for studying defects:

Fig. 1.2 (a) Conoscopic pattern of high-quality sapphire ingot. (b) Conoscopic pattern of sapphire ingot that has a few low-angle boundaries

1. The Berg–Barrett reflection technique [1.37]
2. The double-crystal technique [1.38]
3. The Lang technique [1.36] and its variant – the scanning oscillator technique [1.39]

Following Lang’s work [1.36, 40] in imaging of individual dislocations, x-ray topography has become an important quality-control tool for assessment of semiconductor wafers both before and after device fabrication. Using the scanning oscillator technique developed by Schwutke [1.39], it is possible to record transmission topographs of large-size wafers up to 150 mm in diameter, containing appreciable amounts of elastic and/or frozen-in strain.

Synchrotron X-Ray Topography. The advent of dedicated synchrotron radiation sources has enabled the development of a new field of x-ray topography known as synchrotron topography. Synchrotron radiation is especially suitable for x-ray topography because of the high brightness and low divergence of the x-ray beam. Due to the small source dimensions, low divergence angle, as well as the long source–specimen distance, extremely high resolution can be achieved using synchrotron radiation compared with conventional x-ray topography. For example, based on the geometrical factor, the theoretical resolution obtained can be as low as 0.06 μm . Also, it has numerous advantages over laboratory x-ray topography. One of the most important synchrotron topographic techniques developed is white-radiation topography [1.41]. In APS, the white beam is monochromatized by two cooled parallel Si(111) crystals, and the x-ray energy is tunable in the range 2.4–40 keV.

Crystals as large as 150 mm or even 300 mm in diameter can be imaged by using precision translation stages similar to those used in the Lang technique, and the exposure times are much shorter. If a single crystal is oriented in the beam, and the diffracted beams are

recorded on a photographic detector, each diffraction spot on the resultant Laue pattern will constitute a map of the diffracting power from a particular set of planes as a function of position in the crystal, with excellent point-to-point resolution. There are three common geometries for synchrotron x-ray topography [1.42]:

1. Transmission geometry, also called Laue geometry: In this mode, the x-ray beam passes through the sample and the topographs recorded reveal the bulk defect information of the crystal. Figure 1.3a shows typical transmission synchrotron topography of a 2-inch LED-grade wafer with a very low dislocation density of 10^2 – 10^3 /cm². The topograph shows the dislocation structure in the entire wafer, which shows the presence of basal dislocations.
2. Grazing-incidence reflection geometry: In this configuration, very small incident angle is used [in the case of SiC, typically 2° used and the (11 $\bar{2}$ 8) or (11 $\bar{2}$.12) are recorded]. Grazing incidence is used because of the low penetration depth of the x-ray beam, which is more suitable for studying epilayers.
3. Back-reflection geometry: In this mode, a large Bragg angle is used for basal plane reflection (000 l) (typically 80° for SiC). Screw dislocations along the c -axis and basal plane dislocations within the x-ray penetration depth can be clearly recorded. The wavelength satisfying Bragg condition is automatically selected in white-beam x-ray topography, while in monochromatic synchrotron x-ray topography (XRT), the energy of the x-ray beam has to be preset to satisfy the diffraction condition. Figure 1.3b shows individual screw dislocations and edge dislocation running almost perpendicular to the wafer.

X-ray topographs are typically recorded on Agfa Structurix D3-SC, Ilford L4 nuclear plate, or VRP-M holographic films, depending on the resolution needed.

Exposure time depends on the actual geometry and recording media and varies between a few seconds and 2 h.

Selective Etching

Selective etching is a simple and very sensitive tool for the characterization of single crystals. The usefulness of the etching technique lies in the formation of visible, sharp contrasting etch pits at dislocation sites. The power of etching has been reviewed by several workers [1.31, 43, 44]. The formation of etch pit can be explained as follows. The lattice is distorted for a distance of a few atoms around dislocations. As a result of the stress field generated by the deformation, the lattice elements dissolve more easily at the dislocation sites than in stress-free, undeformed areas. The etch pits are usually straight pyramids with polygonal bases, but other types of pyramids may also be found with various bases and heights. Etch pits can be formed only if certain conditions are satisfied, the most important of these being that the dissolution rate along the surface (V_t) must not greatly exceed the rate of dissolution perpendicular to the surfaces (V_n). The ratio (V_t/V_n) can be increased:

1. By increasing V_n , as has been done in the etchants of several metals
2. By decreasing V_t by adding an inhibitor such as in LiF
3. By varying the temperature to alter the activation energies of V_n and V_t

The etch pits are formed at the dislocation sites, which essentially reveal the emergent point of the dislocations in the surface; they therefore give a direct measure of dislocation density. Since they have certain depths, they also give information on the kind [1.45], configuration, and inclination of dislocations. Etching has also been used to study the stress-velocity rela-

Fig. 1.3 (a) Transmission topograph of high-quality sapphire wafer. (b) Reflection topograph of SiC revealing individual threading screw dislocations running almost perpendicular to the wafer

tions for individual dislocations [1.46]. Movement of dislocations, deformation patterns like pile-up, origin of dislocations in as-grown crystals, polarity of the crystals, grain boundaries, and distribution of dislocations in crystals can be studied [1.44, 45] (Chap. 43). The greatest advantage of this technique is its simplicity and resolution ($0\text{--}10^{12}/\text{cm}^2$). This technique shows the defect density on small areas and hence requires averaging of values taken at a large number of locations. Also, this technique is not a nondestructive method and cannot show the basal plane dislocation when the sample is sliced exactly parallel to the c -axis. Figure 1.4 shows the presence of various defects such as threading edge dislocations, threading screw dislocations, and basal plane dislocations. During the development of SiC crystals, this technique has seen tremendous development and could reveal almost every type of dislocation [1.47].

Microscopy Techniques

Transmission electron microscopy (TEM) (Chap. 44) is a powerful tool to study dislocations when the sample has higher defect density. It is more commonly used for epitaxial films, where large numbers of dislocations originate due to the lattice misfit between the film and the substrate. This method requires tedious sample preparation and is not considered nondestructive.

Decoration is another important technique, where impurity atoms segregate and settle down along dislocation lines during annealing. The decorated dislocations can be observed easily under an optical microscope in transmission mode [1.31].

Growth spirals, which are true manifestations of screw dislocations, can be observed under optical microscopy, scanning electron microscopy (SEM), and atomic force microscopy (AFM). The presence of

Fig. 1.4 Etch pit pattern of SiC wafer revealing threading edge dislocations (TEDs), threading screw dislocations (TSDs), and basal plane dislocations

growth spirals helps to understand the growth mechanism [1.30].

Infrared (IR) microscopy is similar to optical microscopy except for the fact that IR light is used for illumination, with a wavelength comparable to the bandgap of semiconductor materials. This technique is used to study inclusions, cavities, and even dislocations present in the sample [1.48, 49].

Other Techniques

Photoluminescence (PL) [1.50], electron paramagnetic resonance (EPR) (Chap. 45), positron annihilation (Chap. 46), and micro Raman spectroscopy [1.50] are also used to study semiconductor materials and show electronic defect states and the presence of impurities very successfully.

Nucleation at Surfaces

Ivan V. Markov

Part A | 2

This chapter deals with the thermodynamics and kinetics of nucleation on surfaces, which is essential to the growth of single crystals and thin epitaxial films. The starting point is the equilibrium of an *infinitely* large crystal and a crystal with a finite size with their ambient phase. When the system deviates from equilibrium density fluctuations or aggregates acquire the tendency to unlimited growth beyond some critical size – the nucleus of the new phase. The Gibbs free energy change of formation of the nuclei is calculated within the framework of the macroscopic thermodynamics and in terms of dangling bonds in the case of small clusters. In the case of nucleation from vapor the nuclei consist as a rule of very small number of atoms. That is why the rate of nucleation is also considered in the limit of high supersaturations. The effect of defect sites and overlapping of nucleation exclusion zones with reduced supersaturation formed around the growing nuclei is accounted for in determining the saturation nucleus density. The latter scales with the ratio of the surface diffusion coefficient and the atom arrival rate. The scaling exponent is a function of the critical nucleus size and depends on the process which controls the frequency of attachment of atoms to the critical nuclei to produce stable clusters, either the surface diffusion or the incorporation of atoms to the critical nuclei. The nucleation on top of two-dimensional (2-D) islands is considered as a reason for roughening in homoepitaxial growth. The mechanism of formation of three-dimensional (3-D) islands in heteroepitaxial growth is also addressed. The

effect of surface-active species on the rate of nucleation is explored.

Nucleation at surfaces plays a crucial role in the growth of crystals and epitaxial overlayers for the preparation of advanced materials with potential for technological

applications. In homoepitaxy of metal or semiconductor films the instability of planar growth against roughening depends on the kinetics of two-dimensional

nucleation [2.1]. The interplay of wetting and strain leads to clustering in overlayers growing under elastic stress in heteroepitaxy and determines the mechanism of growth and in turn the film morphology [2.2–4]. Smooth quantum wells or self-assembled quantum dots can be grown by varying the conditions of growth (temperature or growth rate) or by use of third species which change both the thermodynamics and kinetics of the processes involved [2.5]. The growth of thin epitaxial films in particular by molecular-beam epitaxy (MBE) usually occurs far from equilibrium. Thus, in addition to thermodynamics, one has to account for the kinetic processes taking place on the crystal surface [2.6]. The latter are responsible for the remarkable richness of patterns which are observed during growth [2.7].

This chapter gives the essential physics of the thermodynamics and kinetics of nucleation, both three- and two-dimensional, on like and unlike substrates as well as some later developments such as the Ehrlich–Schwoebel effect on second-layer nucleation and the effect of surface-active species on nucleation rate. The presentation is oriented more to the needs of experimentalists rather than going deeply into theoretical problems. The chapter is organized as follows. We start with problems of equilibrium of crystals and epitaxial overlayers with the parent phase (vapor, solution) in Sect. 2.1 and consider the equilibrium vapor pressure of infinitely large and finite-size crystals, the thermodynamic driving force for nucleation to occur, and the equilibrium shape of three-dimensional

(3-D) crystals on unlike surfaces. In Sect. 2.2 we define the work for nucleus formation in the most general way and consider the limiting cases of the classical (capillary) theory of nucleation at low or intermediate values of supersaturation and the atomistic approach at high supersaturations. We derive expressions for the work of formation of three-dimensional nuclei on like and unlike substrates. In Sect. 2.3 we give a general formulation of the nucleation rate and again derive expressions valid for high and low supersaturations. We consider further in Sect. 2.4 the saturation nucleus density accounting for the influence of defect (active) sites stimulating nucleation events and the overlapping of undersaturated nucleation exclusion zones around growing clusters. Making use of the rate equation approach we derive expressions for the saturation nucleus density in thin epitaxial films in diffusion and kinetic regimes of growth. In Sect. 2.5 we consider the effect of the step-edge Ehrlich–Schwoebel barrier on second-layer nucleation as a reason for the formation of mounds and thus roughening of surfaces in homoepitaxy. The mechanism of transformation of monolayer-high two-dimensional (2-D) islands into three-dimensional crystallites in Volmer–Weber and Stranski–Krastanov growth is addressed in Sect. 2.6. In Sect. 2.7 we explore the effect of surface-active species on the kinetics of nucleation. Some conclusions and outlook are given in Sect. 2.8.

2.1 Equilibrium Crystal–Ambient Phase

In treating the title problem we use the atomistic approach developed by *Kaischew* and *Stranski* [2.8]. It is based on the assumption of additivity of bond energies and accounts for the elementary processes taking place during growth and dissolution of the particles of the new phase. Although apparently old fashioned this approach is extremely instructive and informative for understanding the essential physics of the equilibrium of infinitely large phases and phases with finite size as well as of the deviation from equilibrium leading to transitions from one phase to another. Numerical studies of the stability of small clusters performed by making use of modern quantum-mechanical methods lead to the same conclusion that the closed atomic structures are most stable [2.9].

2.1.1 Equilibrium of Infinitely Large Phases

We consider for simplicity one-component system. The equilibrium between infinitely large phases (crystal, liquid or vapor) is determined by the equality of the respective chemical potentials. In 1927 *Kossel* and *Stranski* simultaneously developed an atomistic approach which is in fact identical to the definition of the macroscopic thermodynamics [2.10–12]. They considered the different sites that atoms can occupy on the crystal surface and found that there exists one particular site which plays a crucial role in crystal nucleation and growth. They introduced the concept of the *half-crystal position*, which turned out to be intimately connected with the chemical potential of an infinitely large crystal.

Consider the cubic face of a crystal with a simple cubic lattice (a Kossel crystal) containing a monatomic step (Fig. 2.1). Atoms can be located at different sites on the crystal surface. They can be built in the uppermost lattice plane or into the step edge, be adsorbed at the step edge or on the terrace, or can occupy the corner site (3) which has very peculiar properties. An atom in this position is connected with a half-atomic row, a half-crystal plane, and a half-crystal block. This is the reason the term half-crystal position (*Halbkristallage* or kink position) was coined for this particular site. Therefore, the work of separation of an atom from this position is exactly equal to the lattice energy of the crystal per building particle. Hence, the work of detachment of an atom from this position is given by

$$\varphi_{1/2} = \frac{1}{2}(Z_1\psi_1 + Z_2\psi_2 + Z_3\psi_3 \dots),$$

where Z_i are the numbers of neighbors of the consecutive coordination spheres and ψ_i are the respective bond energies.

Whereas atoms in other positions have different numbers of saturated and unsaturated (dangling) bonds, the atom in the kink position (3) has an equal number of saturated and dangling bonds. Therefore, the separation work from a half-crystal position serves as a specific reference with which the probabilities for elementary processes at other sites to take place can be compared. The detachment of an atom from the half-crystal position gives rise to the same position. It follows that, when an atom is detached from this position, the number of dangling bonds remains unchanged and in turn the surface energy does not change. Hence, the whole crystal (if it is large enough to avoid finite-size effects) can be built up or disintegrated into single atoms by repetitive attachment or detachment of atoms to and from this position.

In equilibrium with its vapor the probability of attachment of atoms to this position must be equal to the probability of their detachment. Hence the work of detachment of atoms from this position will determine the equilibrium vapor pressure and in turn its chemical potential. For simple crystals with monatomic vapor the latter will be given at zero temperature (the change of entropy is equal to zero) by

$$\mu_c^\infty = -\varphi_{1/2}, \quad (2.1)$$

where the superscript ∞ indicates an infinitely large crystal.

As seen the chemical potential of an infinitely large crystal is equal to the work of detachment of atoms from

Fig. 2.1 The most important sites an atom can occupy on a crystal surface: 1 – atom embedded into the uppermost crystal plane, 2 – atom embedded into the step edge, 3 – atom in a half-crystal (kink) position, 4 – atom adsorbed at the step, 5 – atom adsorbed on the terrace

the half-crystal position taken with a negative sign. It is this property which makes this position unique in the theory of crystal nucleation and growth [2.13].

There is one more very important property of the half-crystal position. We can divide $\varphi_{1/2}$ into two parts: lateral interaction with the half-atomic row and the half-crystal plane, and the normal interaction with the half-crystal block underneath. If we replace the underlying crystal block by another block of different material and crystal lattice the lateral bonding will remain more or less unchanged if we assume additivity of bond energies. However, the normal bonding will change substantially owing to the difference in both chemical bonding and lattice strain. It is easy to show that the separation work from a kink position in this particular case can be written as

$$\varphi'_{1/2} = \varphi_{1/2} - (\psi - \psi'), \quad (2.2)$$

where ψ' is the energy of a bond between unlike atoms.

Having in mind (2.1), (2.2) can be written as

$$\mu'_c = \mu_c^\infty + (\psi - \psi'). \quad (2.3)$$

We now define the surface energy of a crystal by the following imaginary process. We cleave isothermally and reversibly the crystal into two halves and produce two surfaces with area S . We count the bonds we break

and divide the energy spent by $2S$. If we confine ourselves to nearest-neighbor bonds in the case of Kossel crystal we break one bond per atom and obtain ($S = a^2$)

$$\sigma = \frac{\psi}{2a^2}, \quad (2.4)$$

where a is the atomic diameter.

Using the above definition and the relation of Dupré [2.14]

$$\sigma_i = \sigma_A + \sigma_B - \beta, \quad (2.5)$$

which connects the specific interfacial energy σ_i between the unlike crystals A and B with the specific adhesion energy $\beta = \psi'/a^2$, (2.3) can be written as

$$\mu'_c = \mu_c^\infty + a^2(\sigma + \sigma_i - \sigma_s). \quad (2.6)$$

It is immediately seen that the term in the brackets $\Delta\sigma = \sigma + \sigma_i - \sigma_s$ is in fact the parameter that accounts for the wetting of the substrate (the half-crystal block underneath) by the overlayer in epitaxy of one material on the surface of another [2.15]. Thus, when $\Delta\sigma < 0$, or what is the same, $\psi < \psi'$ (complete wetting), the equilibrium vapor pressure of the first monolayer on the unlike substrate will be smaller than the equilibrium vapor pressure of the bulk crystal ($\mu = \mu_0 + k_B T \ln P$), i.e., $P'_\infty < P_\infty$. This means that at least the first monolayer can be deposited at a vapor pressure smaller than the equilibrium vapor pressure of the bulk crystal, or in other words, at undersaturation, $P'_\infty < P < P_\infty$ [2.16]. If the two crystals have different lattice parameters the growth should continue by formation of three-dimensional (3-D) islands. This is the famous Stranski–Krastanov mechanism of growth [2.17], in which the accumulation of strain energy with film thickness makes the planar film unstable against clustering. Obviously, if the lattice misfit is equal to zero the growth will continue layer by layer in the so-called Frank–van der Merwe mechanism of growth [2.18, 19]. In the opposite case of incomplete wetting ($\Delta\sigma > 0$), 3-D islanding will take place from the very beginning of deposition or Volmer–Weber growth, which requires supersaturation, $P > P_\infty$ [2.20]. We thus see that the separation work from a half-crystal position plays a fundamental role in determining the mechanism of epitaxial growth.

The lattice misfit increases the tendency for 3-D islanding by increasing the interfacial energy in (2.6) with the energy per unit area of misfit dislocations or elastic strain. Thus for heteroepitaxial growth the interfacial energy reads [2.21]

$$\sigma_i^* = \sigma_i + \varepsilon_m,$$

where ε_m is either the misfit dislocation energy or the energy of the homogeneous strain.

Thus the interfacial energy between misfitting crystals consists of two parts: a chemical part σ_i accounting for the difference in chemistry and strength of bonding, and a geometrical part ε_m accounting for the difference of lattices and lattice parameters. If the misfit in heteroepitaxy is accidentally or intentionally tailored to be equal to zero (particularly in binary or ternary alloys) $\varepsilon_m = 0$, but the chemical part σ_i remains different from zero and affects the mechanism of growth.

It should be noted that the misfit plays a decisive role for clustering only in Stranski–Krastanov growth, where it changes the sign of $\Delta\sigma$ from negative to positive beyond the so-called wetting layer. In Volmer–Weber growth $\Delta\sigma$ is positive and the strain energy makes a minor contribution with the same sign to it. Frank–van der Merwe growth takes place only in systems with zero misfit [2.22], which is why we will not take into consideration the effect of lattice misfit in nucleation.

2.1.2 Equilibrium of Small Crystal with the Ambient Phase

The separation work from the half-crystal position cannot determine the equilibrium of a crystal with finite size with its surrounding because the role of the crystal edges and corners cannot be ignored. The kink position is no longer a repetitive step for dissolution of the crystal. That is why Stranski and Kaischew suggested that the condition for a small crystal to be in equilibrium with the ambient phase is for the probability of building up a whole crystal plane to be equal to the probability of its dissolution. In this way the effect of the edge and corner atoms are accounted for in addition to the atoms in half-crystal positions. Obviously, the smaller the crystal, the greater will be the role of the corner and edge atoms, and vice versa. Thus they defined the *mean separation work* as the work per atom to disintegrate a whole crystal plane into single atoms. This quantity must have one and the same value for all crystal faces belonging to the equilibrium shape.

Consider for simplicity a small Kossel crystal with a shape of a cube with edge length $l_3 = an_3$, where n_3 is the number of atoms in the edge of the cube. Confining ourselves to nearest-neighbor bond energy ψ the energy for dissolution of a whole lattice plane into single atoms (by counting the bonds we break in the process of disintegration, Fig. 2.2) is $3n_3^2\psi - 2n_3\psi$. Dividing by the number of atoms n_3^2 the mean separation work

reads [2.8]

$$\bar{\varphi}_3 = 3\psi - \frac{2\psi}{n_3}, \quad (2.7)$$

or, bearing in mind that for a simple cubic lattice $3\psi = \varphi_{1/2}$,

$$\bar{\varphi}_3 = \varphi_{1/2} - \frac{2\psi}{n_3}.$$

It follows that the mean work of separation tends asymptotically to the work of separation from a half-crystal position as the crystal size is increased. We conclude that a crystal can be considered as small if $n_3 < 70$, or $l_3 < 2 \times 10^{-6}$ cm assuming $a \approx 3 \text{ \AA}$.

As $\bar{\varphi}_3$ determines the equilibrium vapor pressure of the small crystal and in turn its chemical potential we can write in analogy with (2.1) for $T = 0$

$$\mu_c = \mu_v = -\bar{\varphi}_3.$$

Then

$$\Delta\mu = \mu_v(P) - \mu_c^\infty(P) = \varphi_{1/2} - \bar{\varphi}_3 = \frac{2\psi}{n_3} \quad (2.8)$$

is the difference of the chemical potentials of the *infinitely large* vapor and crystal phases which represents the thermodynamic driving force for nucleation to occur, or the *supersaturation*.

The equilibrium of the vapor and the crystal takes place at some vapor pressure P_∞ (to stress the fact that the crystal is infinitely large) so that $\mu_v(P_\infty) = \mu_c(P_\infty)$. Then we can write (2.8) as

$$\Delta\mu = [\mu_v(P) - \mu_v(P_\infty)] - [\mu_c(P) - \mu_c(P_\infty)].$$

For small deviations from equilibrium the differences in the above equation can be replaced by derivatives and

$$\Delta\mu = \int_{P_\infty}^P \frac{\partial \mu_v}{\partial P} dP - \int_{P_\infty}^P \frac{\partial \mu_c}{\partial P} dP = \int_{P_\infty}^P (v_v - v_c) dP,$$

where v_v and v_c are the molecular volumes of the vapor and the crystal. As $v_v \gg v_c$ the above equation simplifies to

$$\Delta\mu = \int_{P_\infty}^P v_v dP.$$

Considering the vapor as an ideal gas ($v_v = k_B T / P$) gives upon integration

$$\Delta\mu = k_B T \ln\left(\frac{P}{P_\infty}\right). \quad (2.9)$$

Fig. 2.2a–c Schematic for the evaluation of the mean separation work which determines the equilibrium of a small three-dimensional crystal with the supersaturated vapor phase. In stage (a) we detach $(n-1)^2$ atoms, breaking three bonds per atom, in stage (b) we detach $2(n-1)$ atoms, breaking two bonds per atom, and finally in (c) we detach the last atom, breaking a single bond

The supersaturation $\Delta\mu$ is usually very large in the case of nucleation from vapor, particularly in methods such as MBE. Let us evaluate it for the case of nucleation in MBE growth of Si(111). The supersaturation is given in terms of the ratio of the fluxes R/R_∞ , where $R = P/\sqrt{2\pi mk_B T}$, rather than in vapor pressures as in (2.9). Typical growth conditions are $T = 600$ K and $R = 1 \times 10^{13}$ atom/cm² s [2.23]. The equilibrium vapor pressure of Si at 600 K is $P_\infty = 1.3 \times 10^{-27}$ N/m². Then, $R_\infty \cong 6.5 \times 10^{-8}$ atom/cm² s and $\Delta\mu \cong 2.5$ eV. This means that the supersaturation is of the order of the enthalpy of evaporation of Si (≈ 4.5 eV). As we will see below this is why nuclei consist of a number of atoms of the order of unity.

Note that, with the approximation made, (2.9) is valid for very small deviations from equilibrium. If we repeat the above calculations at much higher temperature, say 1300 K, we find $\Delta\mu \cong 0.05$ eV. We can believe this value to be close to the real figure, but for low temperatures we can be sure only of the sign of the supersaturation (growth or evaporation) but not its numerical value.

Equation (2.8) represents the famous Thomson–Gibbs equation which gives the dependence of the equilibrium vapor pressure of a small crystal on its linear size. Using the definition of the specific surface energy (2.4) we obtain the Thomson–Gibbs equation in its form which is well known in the literature

$$\Delta\mu = \frac{4\sigma v_c}{l_3}. \quad (2.10)$$

We consider further the equilibrium with the vapor phase (and in turn with the dilute adlayer) of a small two-dimensional crystal with a monolayer height formed on the surface of a large three-dimensional crystal. Such an island grows or dissolves by attach-

Fig. 2.3 Schematic for the evaluation of the mean separation work which determines the equilibrium of a small two-dimensional crystal with the supersaturated vapor phase. In equilibrium the probabilities of evaporation and building of a whole row of atoms (*black spheres*) are equal

ment or detachment of whole atomic rows. That is why *Kaischew* and *Stranski* suggested that the probability of building of a whole atomic row with length $l_2 = n_2 a$ is equal to the probability of its disintegration into single atoms [2.8]. The equilibrium 2-D island–vapor phase is now determined by the mean separation work $\bar{\varphi}_2$, which is equal to the energy per atom for evaporation of a whole edge row of atoms (Fig. 2.3). Assuming a square-shaped island with n_2 atoms in the edge the mean separation work reads

$$\bar{\varphi}_2 = 3\psi - \frac{\psi}{n_2} = \varphi_{1/2} - \frac{\psi}{n_2}.$$

The supersaturation necessary for the formation of a two-dimensional island with linear size l_2 then reads

$$\Delta\mu = \frac{\psi}{n_2}. \quad (2.11)$$

Note that in nucleation on surfaces the supersaturation can be expressed as a ratio of the real and the equilibrium adatom concentrations (in equilibrium the chemical potential of the vapor is equal to the chemical potential of the adlayer, which in turn depends on the adatom concentration)

$$\Delta\mu = k_B T \ln\left(\frac{N_1}{N_1^e}\right),$$

where [2.24]

$$N_1^e = N_0 \exp\left(-\frac{\Delta W}{k_B T}\right), \quad (2.12)$$

the difference $\Delta W = \varphi_{1/2} - E_{\text{des}}$ being the work to transfer an atom from a half-crystal position on the surface of a terrace, and N_0 is the atomic density of the crystal surface.

This is particularly true when the adatom concentration is determined by a dynamic adsorption–desorption equilibrium, i.e., when the atom arrival rate R is equal to the re-evaporation rate N_1/τ_s , where $\tau_s = \nu^{-1} \exp(E_{\text{des}}/k_B T)$ is the mean residence time of an atom on the surface before desorption.

We define now the specific edge energy in the same way that we defined the specific surface energy (2.4). We cleave an atomic plane into two halves and produce two edges with length L . We break one bond per atom and for the specific edge energy one obtains

$$\kappa = \frac{\psi}{2a}. \quad (2.13)$$

Combining (2.11) and (2.13) gives the Thomson–Gibbs equation for the two-dimensional case, or the supersaturation required to form an island with edge length l_2 , in its more familiar form [2.24]

$$\Delta\mu = \frac{2\kappa a^2}{l_2}. \quad (2.14)$$

Equations (2.10) and (2.14) can be derived by using the method of thermodynamic potentials introduced by Gibbs (for a review see [2.21]). However, contrary to the pure thermodynamics, the above *molecular-kinetic* or atomistic approach accounts in addition for the elementary processes of growth and dissolution of crystals. The growth of sufficiently large crystal takes place by attachment of building units to the half-crystal position. Once the atom is incorporated at this position we can say that it has joined the crystal lattice. Small three- and two-dimensional crystals grow and dissolve by building and dissolution of whole crystal planes or atomic rows, respectively.

2.1.3 Equilibrium Shape of Crystals

In 1878 *Gibbs* defined thermodynamically the problem of the equilibrium shape of crystals as the shape at which the crystal has a minimum surface energy at given constant volume [2.25]. This definition later acquired a geometric interpretation in the well-known Gibbs–Wulff theorem [2.26], according to which the distances h_n from an arbitrary (Wulff’s) point to the different crystal faces are proportional to the corre-

sponding specific surface energies σ_n of these faces

$$\frac{\sigma_n}{h_n} = \text{const.} \quad (2.15)$$

As a result the equilibrium shape represents a closed polyhedron consisting of the faces with the lowest specific surface energies. The areal extents of the crystal faces belonging to the equilibrium shape have one and the same value of chemical potential.

Half a century later *Kaischew* extended this approach to cover the case of a crystal on a foreign substrate and derived a relation known in the literature as the Wulff–Kaischew theorem [2.27]

$$\frac{\sigma_n}{h_n} = \frac{\sigma_i - \beta}{h_i} = \text{const.}, \quad (2.16)$$

where σ_i is the specific surface energy of the crystal face that is in contact with the substrate and h_i is the distance from the Wulff point to the plane of the contact (Fig. 2.4).

It is seen that the distance from the Wulff point to the contact plane is proportional to the difference $\sigma_i - \beta$. Therefore, when the catalytic potency of the substrate β is equal to zero, the distance h_i will have its value in the absence of a substrate. In this case we have *complete nonwetting*. At the other extreme $\beta = \sigma_A + \sigma_B = 2\sigma$ ($\sigma_A = \sigma_B = \sigma$) we have *complete wetting* and the three-dimensional crystal is reduced to a monolayer-high island. In the intermediate case $0 < \beta < 2\sigma$ we have *incomplete wetting* and the crystal height is smaller than its lateral extent.

The introduction of the separation work from half-crystal position and the mean separation works enabled Stranski and Kaischew to provide a new atomistic approach for determination of the equilibrium shape of crystals. The latter is necessary for calculation of the work of nucleus formation as it is assumed that the nuclei preserve the equilibrium shape as the lowest-energy shape. Thus the lowest-energy pathway of the crystallization process is ensured.

The basic idea is that atoms bound more weakly than an atom in the half-crystal position cannot belong to the equilibrium shape. We start from a sufficiently large crystal with a simple crystallographic form and remove in succession from its surface all atoms bound more weakly than in a half-crystal position. Precisely at that process all the faces of the equilibrium shape appear. Then the areas of the faces are varied by removal and addition of whole crystal planes up to the moment when the mean separation works of all crystal faces become equal. As the mean separation works are closely

Fig. 2.4a–e Equilibrium shape of a crystal on an unlike substrate. The distances h_1 and h_2 in the free polyhedron (a) are proportional to the specific free energies σ_1 and σ_2 according to the Gibbs–Wulff theorem (2.15). In the presence of unlike substrate the distances to free surfaces remain the same as in the free polyhedron. The distance h_i to the plane of contact is determined by the difference $\sigma_i - \beta$ according to the Wulff–Kaischew theorem (2.16). (b) Complete nonwetting ($\beta = 0$); (c, d) different degrees of incomplete wetting (note that in the latter case the vector h_i is negative); (e) complete wetting ($\beta = 2\sigma$)

related to the chemical potentials the latter condition is equivalent to the definition of Gibbs. Thus, during the last operation of equating the mean separation works of all crystal faces, those which do not belong to the equilibrium shape disappear [2.28].

Therefore, the necessary and sufficient condition for the equilibrium shape of a crystal in the molecular-kinetic approach is equality of the mean separation works, or in other words, of the chemical potentials of all crystal faces. We use this condition to derive the equilibrium aspect ratio of a three-dimensional cubic crystal on the surface of an unlike crystal assuming incomplete wetting ($\Delta\sigma > 0$).

Consider a cubic crystal with a square base with edge length $l = na$ and height $h = n'a$, where n and n' are the number of atoms in the horizontal and vertical edges (Fig. 2.5). The mean separation work calculated

Fig. 2.5 A cubic crystal with n and n' atoms in the base and the height on the surface of an unlike crystal at incomplete wetting

from the side crystal face is

$$\bar{\varphi}'_3 = 3\psi - \frac{\psi - \psi'}{n'} - \frac{\psi}{n},$$

whereas the same quantity calculated for the upper base is given by (2.7). The condition $\bar{\varphi}_3 = \bar{\varphi}'_3$ gives

$$\frac{h}{l} = \frac{n'}{n} = \phi, \quad (2.17)$$

where

$$\phi = 1 - \frac{\psi'}{\psi}. \quad (2.18)$$

Substituting ψ and ψ' by the specific surface and adhesion energies and making use of the relation of

Dupré (2.5) gives ϕ in terms of surface energies

$$\phi = \frac{\sigma + \sigma_i - \sigma_s}{2\sigma}. \quad (2.19)$$

As seen, the equilibrium aspect ratio of the crystal is precisely equal to the familiar wetting condition (2.6) relative to 2σ . The parameter ϕ is known in the literature as the *wetting function*; it plays a crucial role in nucleation at surfaces and determines the mechanism of growth of thin epitaxial films [2.15, 29]. It can be shown that (2.19) can be derived by the classical thermodynamic condition of the minimum of the surface energy $\Phi = 4lh\sigma + l^2(\sigma + \sigma_i - \sigma_s)$ at constant volume $V = l^2h$ [2.15].

2.2 Work for Nucleus Formation

2.2.1 General Definition

The nuclei of the new phase represent local fluctuations of the density which can be considered as small molecular aggregates. If the phase is stable the density fluctuations increase the thermodynamic potential of the system. In this sense they are thermodynamically unfavorable. Their concentration is small and they cannot reach considerable size as the probability of decay is greater than the probability of growth. Thus they have no tendency to unlimited growth and can be considered as *lifeless*. Frenkel coined for them the term *homophase fluctuations* to emphasize the fact that they are well compatible with the stable state of aggregation [2.30]. As one approaches the phase equilibrium determined by the equality of the chemical potentials, their concentration increases and the maximum of the size distribution shifts to larger sizes. Once the chemical potential of the initial bulk phase (vapor or solution) becomes greater than that of the new, denser phase (liquid or crystal) the probability of growth becomes greater than the probability of decay and the tendency for growth of the density fluctuations prevails after exceeding some critical size. Frenkel referred to these as *heterophase fluctuations* to stress the fact that they are no longer compatible with the old, less dense phase. It is just these density fluctuations or clusters with a critical size which are called the *nuclei* of the new phase. In order to form such nuclei a free energy should be expended.

Consider a volume containing i_v molecules of a vapor with chemical potential μ_v at constant temperature T and pressure P . The thermodynamic potential

of this initial state is given by $G_1 = i_v\mu_v$. A small crystal with bulk chemical potential μ_c^∞ is formed from i molecules of the vapor phase and the thermodynamic potential of the final state reads $G_2 = (i_v - i)\mu_v + G(i)$, where $G(i)$ is the thermodynamic potential of a cluster consisting of i molecules. The work of formation of a cluster consisting of i molecules is given by the difference $\Delta G(i) = G_2 - G_1$ and [2.31]

$$\Delta G(i) = G(i) - i\mu_v. \quad (2.20)$$

As seen, the work of formation of the cluster represents the difference between the thermodynamic potential of the cluster and the thermodynamic potential of the same number of molecules but in the ambient phase (vapor, solution or melt). This is the most general definition of the work for nucleation. Taking different expressions for $G(i)$ we can approach different cases of nucleation, such as liquid or crystal nuclei, large or small clusters, clusters with or without equilibrium shape, nuclei on like and unlike surfaces, nuclei formed on small particles or ions, etc.

Equation (2.20) is usually illustrated with the simplest case, when the nucleus is a liquid droplet with the (equilibrium) shape of a sphere with radius r surrounded by its own vapor. We assume that the nucleus is sufficiently large that it can be described by macroscopic thermodynamic quantities. This is in fact the classical or capillary approach introduced by Gibbs. He considered nuclei as small liquid droplets, vapor bubbles or crystallites which, however, are sufficiently large to be described by their bulk properties. Although oversimplified, this approach was a significant step ahead

because, when phases with small linear sizes are involved, the surface-to-volume ratio is large.

The thermodynamic potential of the spherical droplet reads

$$G(r) = \frac{4\pi r^3}{3v_l} \mu_l^\infty + 4\pi r^2 \sigma ,$$

where $i = 4\pi r^3/3v_l$ is the number of atoms in the nucleus.

Writing the expression for $G(r)$ in this way we suppose that a cluster with radius r has the chemical potential μ_l^∞ of the infinitely large liquid phase. The second term accounts for the excess energy owing to the newly formed interface between the liquid droplet and the ambient vapor phase, to which we ascribe a specific energy σ that is characteristic of the bulk liquid phase.

The thermodynamic potential of a crystalline cluster with a cubic shape and lateral extent l in the capillary approximation is given by a similar expression

$$G(l) = -\frac{l^3}{v_c} \mu_c^\infty + 6l^2 \sigma . \quad (2.21)$$

Then for the work of nucleus formation in terms of the size l one obtains

$$\Delta G(l) = \frac{l^3}{v_c} \Delta\mu + 6l^2 \sigma , \quad (2.22)$$

where $i = l^3/v_c$, and $\Delta\mu = \mu_v - \mu_c^\infty$ is the supersaturation.

The dependence of $\Delta G(l)$ on the size l is plotted in Fig. 2.6. (Note that the growing cluster preserves its equilibrium shape of a cube with increasing linear size l .) As seen, $\Delta G(l)$ displays a maximum when the ambient phase is supersaturated ($\mu_c^\infty < \mu_v$) at some critical size

$$l^* = \frac{4\sigma v}{\Delta\mu} . \quad (2.23)$$

In the opposite case of undersaturated vapor ($\mu_c^\infty > \mu_v$) both terms in (2.22) are positive and the Gibbs free energy change goes to infinity as the density fluctuations are thermodynamically unfavorable.

Equation (2.23) is in fact the familiar equation (2.10) of Thomson–Gibbs. As discussed above the latter represents the condition of equilibrium of a small particle with its ambient phase. It is important to note that *this equilibrium is unstable*. When more atoms join the nucleus, its size increases and its equilibrium vapor pressure becomes smaller than that of the ambient phase. As a result the probability of growth becomes greater than the probability of decay and the nucleus

Fig. 2.6 Dependence on the crystal size l (or radius r) of the Gibbs free energy change connected with the formation of a crystalline (liquid) nucleus with a cubic (spherical) shape

will continue to grow. If several atoms detach from the nucleus, its equilibrium vapor pressure will increase and become higher than that of the ambient phase. The probability of decay will become dominant and the nucleus will decay further. In other words, any infinitesimal deviation of the size of the nucleus from the critical one leads to a decrease of the thermodynamical potential of the system.

Substituting l^* into (2.22) gives the value of the maximum, or in other words, the change of the Gibbs free energy to form the nucleus

$$\Delta G^* = \frac{32\sigma^3 v^2}{\Delta\mu^2} . \quad (2.24)$$

It is inversely proportional to the square of the supersaturation (a result which was obtained for the first time by Gibbs in 1878 [2.25]) and increases steeply when approaching the phase equilibrium, thus imposing great difficulties for crystallization to take place.

2.2.2 Formation of 3-D Nuclei on Unlike Substrates

Equation (2.21) gives the thermodynamic potential of a small crystallite with a cubic equilibrium shape whose

properties are described in terms of classical macroscopic thermodynamics. In order to relax this restriction Stranski suggested a new approach which can be used for both large crystals and arbitrarily small clusters with arbitrary shape. The thermodynamic potential is given in the more general form

$$G(i) = i\mu_c^\infty + \Phi, \quad (2.25)$$

where Φ plays the role of a surface energy.

The work for nucleus formation then reads

$$\Delta G(i) = -i\Delta\mu + \Phi. \quad (2.26)$$

According to the definition of *Stranski* the *surface* term is given by [2.32]

$$\Phi = i\varphi_{1/2} - U_i, \quad (2.27)$$

where $U_i > 0$ is the energy of disintegration of the whole crystal (or small cluster) into single atoms. In fact $-U_i$ is the potential (binding) energy of the cluster. In the approximation of additivity of bonds energies, U_i is equal to the number of bonds between the atoms of the cluster multiplied by the work ψ to break a single bond.

Equation (2.27) can be easily understood. The first term on the right-hand side gives the energy of the bonds as if all atoms are in the bulk of the crystal (recall that the separation work from the half-crystal position is equal to the lattice energy per atom). The second term gives the energy of the bonds between the atoms of the cluster. Therefore, the difference represents the number of unsaturated (dangling) bonds multiplied by the energy $\psi/2$ of a dangling bond. Obviously, if the cluster is sufficiently large, Φ can be expressed in terms of surface, edge, and apex energies, but as written above it is applicable to arbitrarily small clusters with arbitrary shape.

Combining (2.26) and (2.27) and substituting for $\Delta\mu$ from the Thomson–Gibbs equation (2.8) in atomistic terms in the resulting equation for the Gibbs free energy change for nucleus formation one obtains

$$\Delta G^* = i^* \bar{\varphi}_3 - U_{i^*}. \quad (2.28)$$

We can now calculate the work of formation of a nucleus with equilibrium shape shown in Fig. 2.5. In this case $i = n^2 n'$ and

$$U_i = 3n^2 n' \psi - 2nn' \psi - n^2 \psi \phi, \quad (2.29)$$

where ϕ is the familiar wetting function (2.17) which determines also the equilibrium shape of a crystal on an unlike substrate.

Combining (2.7), (2.28), and (2.29) gives

$$\Delta G^* = n^{*2} \psi \phi, \quad (2.30)$$

where n^* is the number of atoms in the lateral edge of the critical nucleus. Note that $l^* = an^*$ is the length of the edge of the homogeneously formed nucleus in the absence of a substrate or under the condition of complete nonwetting.

We show that (2.30) gives the work of formation of a complete cubic crystallite (2.24) multiplied by the wetting function (2.17), which is positive and smaller than unity in the case of incomplete wetting under study. For this purpose we substitute for n^* and ψ from (2.8) and (2.4), respectively, in (2.30) and obtain ($a^3 = v$)

$$\Delta G^* = \frac{32\sigma^3 v^2}{\Delta\mu^2} \frac{\sigma + \sigma_i - \sigma_s}{2\sigma}, \quad (2.31)$$

where the wetting function ϕ is given in terms of surface energies.

It follows that the work for nucleus formation at surfaces (heterogeneous nucleation) is equal to that of the homogeneously formed nuclei in the absence of a surface multiplied by the wetting function. Bearing in mind that

$$\phi = \frac{h}{l} = \frac{l^2 h}{l^3} = \frac{V}{V_0},$$

we conclude that the ratio of the works for heterogeneous and homogeneous nucleation is equal to the ratio of the respective volumes in the presence and absence of a substrate

$$\Delta G_{\text{het}}^* = \Delta G_{\text{hom}}^* \frac{V}{V_0}.$$

It is interesting to consider the case when a three-dimensional nucleus is formed in the concave edge of a *hill-and-valley* vicinal surface consisting of alternating low-index facets and which is often formed under the effect of adsorbed impurity atoms [2.33,34]. Assuming for simplicity a right angle of the concave edge we find that the nucleus has a prismatic equilibrium shape, having two edges with length $l' = n'a$ and one edge with a length $l = na$. Using the same procedure as before for ΔG^* one obtains

$$\Delta G^* = n^{*2} \psi \phi^2$$

or

$$\Delta G^* = \frac{32\sigma^3 v^2}{\Delta\mu^2} \left(\frac{\sigma + \sigma_i - \sigma_s}{2\sigma} \right)^2.$$

In the same way we find that the work of formation of a nucleus in a right-angle corner is proportional to the third degree of the wetting function ϕ , etc. As $\phi < 1$ we conclude that a rough surface containing concave edges and corners stimulates nucleation by decreasing the nucleus volume.

2.2.3 Work of Formation of 2-D Crystalline Nuclei on Unlike and Like Substrates

To solve this problem we apply the same procedure, bearing in mind that we have to account for the mean separation work for a two-dimensional square cluster. We consider first the more general case in which the 2-D nucleus is formed on an unlike substrate. Obviously, in order for the 2-D nucleus to be stable the wetting should be complete, although 2-D nuclei can be stable in incomplete wetting but only up to some critical size [2.35]. Beyond this size the monolayer islands become unstable against bilayer islands and should be rearranged into three-dimensional islands as required by the thermodynamics (Sect. 2.6).

The mean separation work calculated for a 2-D square nucleus consisting of $i = n^2$ atoms on unlike substrates reads

$$\bar{\varphi}'_2 = 3\psi - \frac{\psi}{n} - \psi\phi$$

and

$$\Delta\mu = \frac{\psi}{n} + \psi\phi. \quad (2.32)$$

The binding energy is $U_i = 3n^2\psi - 2n\psi - n^2\psi\phi$ and the Gibbs free energy change reads

$$\Delta G^* = n^*\psi. \quad (2.33)$$

Substituting for n^* from (2.32) and ψ from (2.13) in (2.33) gives

$$\Delta G^* = \frac{\psi^2}{\Delta\mu - \psi\phi} = \frac{4\kappa^2 a^2}{\Delta\mu - a^2(\sigma + \sigma_i - \sigma_s)}. \quad (2.34)$$

In the limiting case of a like substrate (nucleation on the surface of the same crystal) $\Delta\sigma = \sigma + \sigma_i - \sigma_s = 0$ and the Gibbs free energy change reads

$$\Delta G^* = \frac{\psi^2}{\Delta\mu} = \frac{4\kappa^2 a^2}{\Delta\mu}. \quad (2.35)$$

Substituting for ψ from the Thomson–Gibbs equation (2.32) in the case of complete wetting, $\phi = 0$, in (2.35) one obtains the very useful result that the work

for nucleus formation is precisely equal to the volume part of it

$$\Delta G^* = n^{*2} \Delta\mu = i^* \Delta\mu. \quad (2.36)$$

Equations (2.34) and (2.35) lead to some interesting conclusions. In the case of incomplete wetting ($\Delta\sigma > 0$) 2-D nucleation can take place only at supersaturation higher than $\Delta\mu_0 = a^2\Delta\sigma$, because when approaching the latter the work for nucleus formation goes to infinity. In the case of complete wetting ($\Delta\sigma < 0$) both terms in the denominator of (2.34) are positive and 2-D nucleation can take place even at undersaturation. As follows from (2.35) a 2-D nucleation event on the surface of the same crystal ($\Delta\sigma = 0$) can occur only at supersaturations higher than zero.

Equations (2.31) and (2.34) give another critical supersaturation $\Delta\mu_{cr} = 2\Delta\mu_0$ at which the 3-D nucleus is reduced to a 2-D nucleus with monolayer height. The reason is that, assuming a constant equilibrium aspect ratio $h/l < 1$, on decreasing the nucleus size with increasing supersaturation a moment comes when the thickness of the 3-D island becomes equal to one monolayer [2.36–38]. As a result three-dimensional nucleation should not take place at supersaturations larger than $\Delta\mu_{cr}$. The latter does not contradict the observed layer-by-layer growth of Pb on Ge(001) at 130 K [2.39].

In the end of this subsection we will briefly discuss the very interesting and important question of the existence and formation of one-dimensional nuclei. The latter can be considered as rows of atoms at the edge of a single height step. Using the approach of the mean separation works the equilibrium of a such row of atoms with the ambient phase will be given by the equality of the probabilities of attachment and detachment of atoms to the row's ends. However, the row's ends represent half-crystal positions, so the *mean separation work* reads $\bar{\varphi}_1 = 3\psi = \varphi_{1/2}$ and the supersaturation is $\Delta\mu = \varphi_{1/2} - \bar{\varphi}_1 = 0$. The latter means that a row of atoms has the same chemical potential as the bulk crystal, irrespective of its length. The potential energy of a row consisting of i atoms is $U_i = 3i\psi - \psi$, and the work of formation of a one-dimensional nucleus is $\Delta G_1^* = i\bar{\varphi}_1 - U_i = \psi$. As seen ΔG_1^* does not depend on the row's length, which means that a critical size as in 3-D and 2-D nucleation does not exist. All the above means that one cannot define thermodynamically one-dimensional nuclei. However, as pointed out by several authors, one-dimensional nuclei can be well defined kinetically [2.40–42]. It is in fact the formation of one-dimensional nuclei which allows the propagation of smooth steps, particularly at low temperatures.

We mention here only two cases of great practical importance: the advancement of S_A steps on the surface of Si(001) 2×1 [2.43, 44] and the growth of protein crystals [2.45]. We would like to stress once more that the one-dimensional nucleation is a purely kinetic process and a critical size cannot be defined thermodynamically.

2.3 Rate of Nucleation

As discussed above the equilibrium of a small particle of the new phase with the supersaturated ambient phase is unstable. Accidental detachment of atoms from the critical nucleus can result in a decay of the cluster even to single atoms. Attachment of several atoms could lead to unlimited growth. It is not accidental that the exact solution of the time-dependent problem leads to a diffusion-type equation which reflects the random character of the processes of growth and decay around the critical size [2.30]. We can thus interpret the growth of the clusters as a *diffusion* in the space of the size. We conclude that nucleation is a random process. The steady-state rate of nucleation is a constant quantity which represents an average in time of randomly distributed events.

2.3.1 General Formulation

Becker and Döring advanced a purely kinetic approach which allowed them to derive a general expression for the steady-state nucleation rate making the assumptions of: (1) steady-state distribution of the heterophase fluctuations, (2) constant geometrical shape of the growing clusters which coincides with the equilibrium shape, and (3) constant supersaturation which is achieved by removal of clusters which are sufficiently large (much larger than the critical nucleus, $I \gg i^*$) from the system and then are returned back as single atoms [2.46]. The interested reader is referred to the excellent analysis of Christian [2.47]. Relaxing assumption 2 did not affect significantly the final result, whereas allowing variable supersaturation changed only the transient character of nucleation but not the steady-state nucleation rate [2.48]. It was in fact the first assumption which played the essential role in solving the problem.

Becker and Döring considered the nucleation process as a series of consecutive bimolecular reactions (a scheme proposed by Leo Szilard)

in which the growth and decay of the clusters take place by attachment and detachment of single atoms. Triple and multiple collisions are excluded as less probable. ω_i^+ and ω_i^- denote the rate constants of the direct and reverse reactions. Here \mathcal{A} is used as a chemical symbol.

Clusters consisting of i atoms are formed by the growth of clusters consisting of $i-1$ atoms and the decay of clusters of $i+1$ atoms (birth processes) and disappear by the growth and decay into clusters of $i+1$ and $i-1$ atoms (death processes), respectively. Then the change with time of the concentration $Z_i(t)$ of clusters consisting of i atoms is given by

$$\frac{dZ_i(t)}{dt} = J_i(t) - J_{i+1}(t),$$

where

$$J_i(t) = \omega_{i-1}^+ Z_{i-1}(t) - \omega_i^- Z_i(t) \quad (2.37)$$

is the net flux of clusters through the size i .

Assuming a steady-state concentration of the clusters in the system, $dZ_i(t)/dt = 0$, leads to

$$J_i(t) = J_{i+1}(t) = J_0,$$

where we denote by J_0 the time-averaged frequency of formation of clusters of any size. Therefore, J_0 is also equal to the frequency of formation of the clusters with the critical size i^* and thus is equal to the steady-state nucleation rate.

Applying a simple mathematical procedure to the system of rate equations which describe the scheme of Szilard for J_0 one obtains [2.49]

$$J_0 = Z_1 \sum_{i=1}^{I-1} \left(\frac{1}{\omega_i^+} \frac{\omega_2^- \omega_3^- \dots \omega_i^-}{\omega_1^+ \omega_2^+ \dots \omega_{i-1}^+} \right)^{-1}. \quad (2.38)$$

This is the most general expression for the steady-state rate of nucleation. It is applicable to any case of nucleation (homogeneous or heterogeneous, from

any ambient phase – vapor, solution or melt, three- or two-dimensional, etc.). It also allows the derivation of equations for the classical as well as the atomistic nucleation rate at small and high supersaturations as limiting cases. The only thing we should know in any particular case are the rate constants ω_i^+ and ω_i^- .

The analysis of (2.38) shows that every term in the sum is equal to $\exp(\Delta G(i)/k_B T)$, where $\Delta G(i)$ is the work to form a cluster consisting of i atoms [2.50]

$$\frac{\omega_2^- \omega_3^- \dots \omega_i^-}{\omega_1^+ \omega_2^+ \dots \omega_{i-1}^+} = \exp\left(\frac{\Delta G(i)}{k_B T}\right). \quad (2.39)$$

The condition of an imaginary equilibrium $J_0 = 0$ applied to (2.37) leads to an equation known in the literature as the equation of *detailed balance*

$$\frac{N_i}{N_{i-1}} = \frac{\omega_{i-1}^+}{\omega_i^-},$$

where N_i denotes the equilibrium concentration of clusters consisting of i atoms. Multiplying the ratios N_i/N_{i-1} from $i = 2$ to i gives an expression for the equilibrium concentration of clusters of size i

$$\frac{N_i}{N_1} = \prod_{n=2}^i \left(\frac{\omega_{n-1}^+}{\omega_n^-} \right) = \left(\frac{\omega_2^- \omega_3^- \dots \omega_i^-}{\omega_1^+ \omega_2^+ \dots \omega_{i-1}^+} \right)^{-1}. \quad (2.40)$$

Substituting (2.39) into (2.40) gives for the *equilibrium concentration of clusters of size i*

$$N_i = N_1 \exp\left(-\frac{\Delta G(i)}{k_B T}\right). \quad (2.41)$$

We recall that $\Delta G(i)$ displays a maximum at $i = i^*$. It follows that N_i should display a minimum at the critical size.

Substituting (2.39) into (2.38) and replacing the summation by integration valid for large critical nuclei one obtains

$$J_0 = \omega^* \Gamma N_{i^*},$$

where $\omega^* \equiv \omega_{i^*}$ is the frequency of attachment of atoms to the critical nucleus, $\Gamma = (\Delta G^*/3\pi k_B T i^{*2})^{1/2}$ is the so-called nonequilibrium Zeldovich factor which accounts for neglecting processes taking place far from the critical size, and N_{i^*} is given by (2.41) for the critical nucleus. It is assumed that the equilibrium monomer concentration N_1 is equal to the steady-state concentration Z_1 .

In the particular case of nucleation on surfaces we have to account for the configurational entropy of

distribution of clusters and single atoms among the adsorption sites of density N_0 ($\approx 1 \times 10^{15} \text{ cm}^{-2}$) which should be added to the Gibbs free energy changes (2.31), (2.34) or (2.35) [2.51]. Assuming that the density of clusters is negligible compared with that of single atoms the entropy correction reads

$$\Delta G_{\text{conf}} \approx -k_B T \ln\left(\frac{N_0}{N_1}\right).$$

Then for the steady-state nucleation rate on surfaces one obtains

$$J_0 = \omega^* \Gamma N_0 \exp\left(-\frac{\Delta G^*}{k_B T}\right), \quad (2.42)$$

where the frequency of attachment of atoms to the critical nucleus ω^* accounts only for the surface diffusion of atoms to the nucleus, the direct impingement from the vapor being neglected [2.52].

As discussed above the capillary nucleation theory is valid at supersaturations which are sufficiently low that the nuclei are large and can be described in terms of the classical thermodynamics. In order to find the limits of validity of (2.42), or in other words, the maximum value of the supersaturation at which the above equation is still valid, we have to find the values of the pre-exponential $K = \omega^* \Gamma N_0$ and ΔG^* and calculate the time τ elapsed from *switching on* the supersaturation to the appearance of the first nucleus. The latter is given by $\tau = 1/J_0 S$, where S is the area available for nucleation.

Consider for simplicity 2-D nucleation on the surface of the same crystal. The frequency of attachment of atoms to the critical nucleus ω^* is given by the product of the periphery of the nucleus and the flux of adatoms joining the nucleus. We assume that the nucleus consists of at least 49 atoms (a square of 7×7 atoms) in order for the classical theory to be valid. The flux of adatoms to the periphery is $j_s \approx D_s N_1 / a$, where $D_s = a^2 \nu \exp(-E_{sd}/k_B T)$ is the surface diffusion coefficient, and the adatom concentration is determined by a dynamic adsorption–desorption equilibrium and is given by $N_1 = R\tau_s$. The reason for using this definition is that it is supposed that the temperature is sufficiently high to ensure low supersaturation and the desorption flux N_1/τ_s is significant. Here ν is the attempt frequency and E_{sd} and E_{des} are the activation barriers for surface diffusion and desorption, respectively. Taking appropriate values for the parameters involved we find a value for the pre-exponential of the order of $10^{20} - 10^{25} \text{ cm}^{-2} \text{ s}^{-1}$ for nucleation from vapor. We can further evaluate the supersaturation by using (2.11).

Once we know the supersaturation we can easily evaluate ΔG^* by making use of (2.36).

We consider as an example nucleation on Si(001) at $T = 1500$ K and assume that $S = 1 \text{ cm}^2$, although a more realistic value could be determined from the width of the terraces on the crystal surface. From the enthalpy of evaporation we deduce the bond strength to be of the order of $2\text{--}2.2 \text{ eV}$. Then $\Delta\mu \approx 0.3 \text{ eV}$, $\Delta G^* = 15 \text{ eV}$, and $\tau \approx 1 \times 10^{15}$ millennia. This behavior of the classical nucleation rate was noticed by *Dash*, who noted that nucleation on defectless crystal surfaces according to the classical theory requires *astronomically* long times [2.53]. The reason for this behavior is that the pre-exponential in J_0 is a very weak function of the supersaturation compared with the exponential $\exp(-\Delta G^*/k_B T)$, which varies very

steeply with the latter. As a result there is a critical supersaturation below which the rate of nucleation is practically equal to zero and beyond which it takes values of many orders of magnitude (Fig. 2.7). We conclude that, in order for a nucleation event to take place on a laboratory scale of time, $\Delta G^*/k_B T$ should be smaller than ≈ 30 (in the case under consideration it is 4 times larger). This means that, for most materials at working temperatures between 600 and 1000 K, *the number of atoms in the critical nucleus should be of the order of unity*. This is why we will develop in more detail the atomistic theory of nucleation valid for nuclei consisting of very small number of atoms. It is important to note that a small value (usually not larger than ten) of the number of atoms in the critical nucleus should be expected also in the case of three-dimensional nucleation. A value of $i^* = 9$ was obtained in the case of nucleation of CoSi_2 from amorphous Co-Si alloy [2.54]. The reason for the comparatively larger size is due to the much greater value of the pre-exponential, which in this particular case is on the order of $10^{35}\text{--}10^{40} \text{ cm}^{-3} \text{ s}^{-1}$ [2.21].

2.3.2 Rate of Nucleation on Single-Crystal Surfaces

Single-crystal surfaces always represent vicinal surfaces consisting of terraces divided by steps due to the tilt of the surface by some small angle with respect to the low-index (singular) crystal face. Numerous processes can take place during deposition on the terraces (Fig. 2.8). We consider first the case of complete wetting. Atoms arrive from the vapor and accommodate thermally with the substrate [2.55], diffuse on the crystal surface, and re-evaporate if the temperature is sufficiently high. The atoms can also join pre-existing steps and diffuse along these steps to incorporate into kink sites. The reverse process of detachment of atoms from kink sites directly to the terrace or through the intermediate state of adsorption at the step edge can also take place. Thus when the temperature is sufficiently high the crystal grows by propagation of the pre-existing steps. If the temperature is low and the atom diffusivity is small the atoms cannot reach the steps and collide with other atoms to produce dimers. The dimers can grow further to produce trimers, tetramers, and finally large islands by attachment of new adatoms, or can decay into single atoms. Arriving atoms will preferably join the islands in a later stage of growth, the formation of new dimers being inhibited. Thus we can distinguish two

Fig. 2.7 Plot of the nucleation rate versus the supersaturation. The nucleation rate is practically equal to zero up to a critical supersaturation $\Delta\mu_c$. Beyond this value the rate of nucleation increases sharply by many orders of magnitude

Fig. 2.8 Schematic representation of the different processes which can take place on surfaces during deposition on like and unlike substrates: 1 – adsorption, 2 – surface diffusion, 3 – desorption, 4 – edge diffusion, 5 – transformation of monolayer to bilayer island in heteroepitaxy, 6 – dimer formation, 7 – dimer decay, 8 – step-down hopping, 9 – step-up jump

regimes of growth: step flow growth at high temperatures and growth by two-dimensional nucleation at low temperatures.

In the case of incomplete wetting which favors three-dimensional clustering all the processes listed above remain the same with the exception that step flow growth does not take place (we consider the case of heteroepitaxy with $\psi > \psi'$); nucleation occurs at all temperatures. The mechanism of formation of 3-D clusters depends strongly on the wetting. In the extreme of very weak wetting (metals on alkali halides) visible clustering is observed from the very beginning of deposition. When the wetting is stronger as in the technologically important cases of metals on metals or semiconductors on semiconductors, two-dimensional islands are initially energetically favored but become unstable and transform beyond some critical size into 3-D clusters (Fig. 2.8) [2.35]. The same is observed in Stranski–Krastanov growth beyond the wetting layer [2.56, 57]. Thus in the beginning of deposition the overlayer can be considered as a population of molecules of different size, most of which are one atom high [2.58].

2.3.3 Equilibrium Size Distribution of Clusters

We calculate first the equilibrium concentration of the clusters of size i . The thermodynamic potential of the cluster of size i is given by (2.25), where i is an integer which can be arbitrarily small. Bearing in mind (2.26)

and (2.27) the work for nucleus formation reads

$$\Delta G(i) = G(i) - i\mu_v = i(\phi_{1/2} - \Delta\mu) - U_i. \quad (2.43)$$

Assuming the adlayer consisting of clusters of different size behaves as a two-dimensional ideal gas ($\sum_i N_i \ll N_0$) the thermodynamic potential of the population of clusters of size i will be [2.59]

$$\mathcal{G}(N_i) = N_i G(i) - k_B T \ln \frac{N_0!}{(N_0 - N_i)! N_i!}.$$

Then for the chemical potential of the two-dimensional ideal gas of clusters of size i one obtains

$$\mu_i = \frac{d\mathcal{G}(N_i)}{dN_i} = G(i) - k_B T \ln \left(\frac{N_0}{N_i} \right). \quad (2.44)$$

Suppose now that the pressure of the vapor is precisely equal to the equilibrium vapor pressure of the infinitely large crystal at the given temperature so that $\mu_i = i\mu_c^\infty$. The system is in a true equilibrium and the nucleation rate is precisely equal to zero. Rearranging (2.44) and inserting the above equality gives for the equilibrium concentration of i -atomic clusters

$$\frac{N_i^e}{N_0} = \exp \left(- \frac{G(i) - i\mu_c^\infty}{k_B T} \right).$$

Assume now that the vapor pressure is higher than the equilibrium vapor pressure so that $\mu_i = i\mu_v > i\mu_c^\infty$. The system will be supersaturated and the nucleation rate will differ from zero. We apply as before the artificial condition $J_0 = 0$, which determines a hypothetical equilibrium concentration of clusters of size i

$$\frac{N_i}{N_0} = \exp \left(- \frac{G(i) - i\mu_v}{k_B T} \right).$$

Substituting for $G(i)$ from (2.43) in the above equation gives

$$\frac{N_i}{N_0} = \exp\left(-\frac{i\varphi_{1/2} - i\Delta\mu - U_i}{k_B T}\right). \quad (2.45)$$

The condition $i = 1$ yields the density of monomers

$$\frac{N_1}{N_0} = \exp\left(-\frac{\varphi_{1/2} - \Delta\mu - U_1}{k_B T}\right),$$

the i -th power of which reads

$$\left(\frac{N_1}{N_0}\right)^i = \exp\left(-\frac{i\varphi_{1/2} - i\Delta\mu - iU_1}{k_B T}\right). \quad (2.46)$$

Dividing (2.45) and (2.46) gives for this hypothetical equilibrium concentration of clusters of size i [2.58]

$$\frac{N_i}{N_0} = \left(\frac{N_1}{N_0}\right)^i \exp\left(\frac{E_i}{k_B T}\right), \quad (2.47)$$

where $E_i = U_i - iU_1$ is the net energy gained to form an i -atom cluster from i single atoms. Bearing in mind that U_1 is, in fact, the adhesion energy ψ' , E_i is the potential (binding) energy of the lateral bonds in the cluster. The latter means that the value of E_i does not depend (within the framework of the approximation of the additivity of the bond energies) on the material of the substrate. It should be one and the same on like and unlike substrate crystals. Recall that we defined U_i as a positive quantity. This means that E_i is also positive. As $N_1/N_0 \ll 1$ the pre-exponential decreases whereas the exponential increases with i . It follows that (2.47) should display a minimum at some critical size or, in other words, will have the same qualitative behavior as the classical equilibrium size distribution (2.41).

2.3.4 Rate of Nucleation

An approximate expression for the nucleation rate can be obtained by multiplying (2.47) by the flux of atoms to the critical nucleus. Note, however, that in the case of small clusters the classical definition of a nucleus as a cluster with equal probabilities for growth and decay, each one equal to 0.5, is not valid. The nucleus should be defined as the cluster whose probability of growth is smaller than or equal to 0.5, but which after attachment of one more atom will have a probability of growth greater than or equal to 0.5 [2.58]. The latter is called the *smallest stable cluster*. Thus the nucleation rate is the rate at which clusters of critical size become *supercritical* or smallest stable clusters.

It is clear that for small clusters the requirement of constant geometrical shape required by the classical theory is violated. An analytical expression for i^* cannot be derived and the nucleus structure should be determined by a trial-and-error procedure by estimating the binding energy of the different configurations including the possibility of formation of three-dimensional structures. Let us consider as an example the formation of nuclei on the (111) surface of a face-centered cubic (fcc) metal (Fig. 2.9). At $\Delta\mu = 3.25\psi$ the critical nucleus consists of two atoms and the smallest stable cluster consists of three atoms (Fig. 2.10). The work required to decay the nucleus is equal to the work to break a single first-neighbor bond, whereas in order to detach an atom from the smallest stable cluster we have to break simultaneously two first-neighbor bonds. This means that the latter will be much more stable than the nucleus and a higher temperature is required to decay the three-atom cluster. The attachment of additional atoms up to $i = 6$ does not change the stability of the respective clusters. Then at $\Delta\mu = 2.75\psi$ the nucleus consists of six atoms and the smallest stable cluster represents

Fig. 2.9a–d Two-dimensional clusters on (001) and (111) surfaces of a crystal with a face-centered cubic lattice. The structure of the nuclei is given by the *gray circles*. The *black circles* denote the atoms that turn the critical nuclei into smallest stable clusters. **(a)** The nucleus consists of a single atom; the stable supercritical cluster is a dimer, which requires a single bond to be broken in order to decay. In **(b)** the nucleus consists of three atoms situated on the apexes of a rectangular triangle on (001) surface; the smallest stable cluster has a square shape. The decay of the latter requires the simultaneous breaking of two bonds. On (111) surface the nuclei consist of **(a)** one, **(c)** two, and **(d)** six atoms. The corresponding stable clusters consist of two, three, and seven atoms, respectively, which require breaking of one, two, and three bonds

a closed structure consisting of a complete ring of six atoms plus an atom in the middle. In order to detach an atom from the smallest stable cluster we have to break simultaneously three first-neighbor bonds. Obviously, such a cluster will be stable at much higher temperatures than a three-atom cluster.

Bearing in mind that every term in the sum of (2.38) is equal to $\exp(\Delta G(i)/k_B T)$ we study the behavior of the latter for small values of i (Fig. 2.10). It is seen that at extremely high supersaturations (low temperatures) $\Delta G(i)$ and $\exp(\Delta G(i)/k_B T)$ are represented by broken curves whereas at low supersaturations (large nuclei) the curve is smooth. Contrary to the classical case where the clusters in the vicinity of the critical size have values of $\exp(\Delta G(i)/k_B T)$ close to that of the nucleus, in the case of small clusters the contribution of $\exp(\Delta G(i^*)/k_B T)$ of the critical nucleus is the largest, all other terms in the sum of the denominator being negligible. Thus, instead of summing all the terms as in the classical theory, we can take the largest term and neglect all the others. For this purpose we write (2.38) in the form

$$J_0 = \omega_1^+ N_1 \left(1 + \frac{\omega_2^-}{\omega_2^+} + \frac{\omega_2^- \omega_3^-}{\omega_2^+ \omega_3^+} + \frac{\omega_2^- \omega_3^- \omega_4^-}{\omega_2^+ \omega_3^+ \omega_4^+} + \dots \right)^{-1} \quad (2.48)$$

and calculate the rate constants for the birth and death processes.

By analogy with the classical theory, where $\omega_i^+ \approx (P_i/a) D_s N_1$, P_i being the perimeter of the nucleus and P_i/a the number of the dangling bonds, in the atomistic approach [2.60]

$$\omega_i^+ = \alpha_i D_s N_1,$$

where α_i is the number of ways of attachment of an atom to a cluster of size i to produce a cluster of size $i+1$. Obviously, this parameter is proportional to the number of dangling bonds.

The decay constant reads

$$\omega_i^- = \beta_i \nu \exp\left(-\frac{E_i - E_{i-1} + E_{sd}}{k_B T}\right), \quad (2.49)$$

where E_i is the work to disintegrate a cluster of size i into single atoms, and $E_i - E_{i-1}$ is the work required to detach an atom from the cluster of size i . β_i is the number of ways of detachment of an atom from a cluster of size i . It is easy to show that there exists a one-to-one correspondence between the growth ($i \rightarrow i+1$) and decay ($i+1 \rightarrow i$) processes so that

$$\alpha_i = \beta_{i+1}.$$

Fig. 2.10a,b Dependence of (a) the Gibbs free energy change $\Delta G(i)/\psi$ in units of the work ψ required to break a first-neighbor bond, and (b) $\exp(\Delta G(i)/k_B T)$ on the number of atoms i in the cluster at different values of the supersaturation. At small supersaturation ($\Delta\mu = 0.02\psi$) the cluster is large, the respective curves are smooth, and the summation can be replaced by integration. At very large supersaturations the curves are broken and the contribution of the critical nucleus is dominant

Recalling the expression for the diffusion coefficient $D_s = a^2 \nu \exp(-E_{sd}/k_B T)$ we can write (2.49) in the form

$$\omega_i^- = \beta_i D_s N_0 \exp\left(-\frac{E_i - E_{i-1}}{k_B T}\right),$$

where $N_0 \cong a^{-2}$.

The assumption that all terms in the denominator in (2.48) are smaller than unity means that $i^* = 1$

Fig. 2.11 Experimental data for the nucleation rate as a function of the overpotential η in the case of electrochemical nucleation of mercury on platinum single-crystal spheres (after [2.61]), in atomistic coordinates $\ln J_0 - \eta$, according to [2.62]. The number of atoms in the critical nucleus changes at about 0.096 V

($E_1 = 0$) and

$$J_0 = \omega_1^+ N_1 = \alpha_1 D_s N_1^2.$$

Assuming that the adatom concentration is determined by a dynamic adsorption–desorption equilibrium $N_1 = R\tau_s$ as before, for J_0 one obtains

$$J_0 = \alpha_1 \frac{R^2}{N_0 v} \exp\left(\frac{2E_{\text{des}} - E_{\text{sd}}}{k_B T}\right).$$

When the ratio ω_2^-/ω_2^+ is the largest term in the denominator of (2.48), $i^* = 2$ and

$$J_0 = \omega_1^+ N_1 \frac{\omega_2^+}{\omega_2^-} = \alpha_2 D_s^2 N_1^3 v^{-1} \exp\left(\frac{E_2 + E_{\text{sd}}}{k_B T}\right)$$

or

$$J_0 = \alpha_2 \frac{R^3}{N_0^2 v^2} \exp\left(\frac{E_2 + 3E_{\text{des}} - E_{\text{sd}}}{k_B T}\right).$$

In the general case

$$J_0 = \alpha^* R \left(\frac{R}{N_0 v}\right)^{i^*} \times \exp\left(\frac{E_{i^*} + (i^* + 1)E_{\text{des}} - E_{\text{sd}}}{k_B T}\right).$$

Very often the process of re-evaporation is negligible (complete condensation) and $N_1 \neq R\tau_s$. Then we can write J_0 in terms of the adatom concentration in the form

$$J_0 = \alpha^* D_s \frac{N_1^{i^*+1}}{N_0^{i^*-1}} \exp\left(\frac{E_{i^*}}{k_B T}\right), \quad (2.50)$$

which is very useful for solving various nucleation problems.

Whereas the attachment or detachment of atoms to and from a comparatively large liquid droplet or crystallite can be considered as a good approximation to a continuous process, this is impossible when the cluster consists of several atoms. In this case the general principles of the thermodynamics are violated, the best example of which is that the Thomson–Gibbs equation is not valid in its familiar form (2.10). The reason becomes obvious if we write it in terms of the number of atoms rather than the linear size of the crystallite

$$\frac{P_i}{P_\infty} = \exp\left(\frac{4\sigma v^{2/3}}{k_B T i^{1/3}}\right).$$

It is immediately seen that the vapor pressure in the left-hand side of the equation can be continuously varied whereas the right-hand side is a discrete function of the cluster size i . The latter means that to any particular size of the cluster corresponds a fixed value of the vapor pressure, but the opposite is not true; an integer number of atoms does not correspond to any arbitrary value of the vapor pressure. It follows that, contrary to the classical concept, a cluster with an integer number of atoms is stable in an interval of supersaturation (or vapor pressure) which becomes larger as the cluster size becomes smaller [2.63]. This interval is equal to $P_i - P_{i+1}$, where P_i is the fixed value of the vapor pressure corresponding to a cluster consisting of i atoms.

Substituting for ΔG^* from (2.26) with $i = i^*$ in (2.42) gives

$$J_0 = \omega^* \Gamma N_0 \exp\left(-\frac{\Phi}{k_B T}\right) \exp\left(i^* \frac{\Delta\mu}{k_B T}\right).$$

As the shape does not change at constant number of atoms the *surface* part Φ remains constant in the interval of stability of a given cluster size. Then the logarithm of the nucleation rate as a function of the supersaturation will represent a broken line when the supersaturation interval is sufficiently wide to cover the intervals of several cluster sizes. The slopes of the consecutive straight line parts will be equal to the respective number of atoms i^* of the critical nuclei. This is shown in Fig. 2.11, which represents experimental data for the nucleation rate in electrodeposition of mercury on platinum single-crystal spheres [2.61], interpreted in terms of the atomistic theory in [2.62] (see also [2.64]). The values $i^* = 6$ and 10 have been found from the slopes of the two parts of the plot. A clear evidence for a transition from

$i^* = 1$ to $i^* = 3$ has been reported by Müller et al. in the case of nucleation of Cu on Ni(001) [2.65]. Thus a single nucleus size is operative over a temperature (supersaturation) interval. The slopes of the consecutive intervals give a distinct series of consecutive numbers of atoms which depend on the crystallographic orientation of the substrate. Thus in the case of nucleation of (001) surface of fcc metals the numbers are one and three, whereas on (111) surface the numbers are one, two, and six. The corresponding smallest stable clusters ($i^* + 1 = 2, 3, 7$ on the fcc(111) surface) are often referred to as *magic* in the literature. The physics behind this magic is simple. In order to detach an atom from the corresponding smallest stable clusters we have to break simultaneously one, two or three bonds.

2.4 Saturation Nucleus Density

Measurements of the nucleus density as a function of time show that, after sufficiently long time, the nucleus density saturates; this means that the nucleation process ceases. Numerous factors can be responsible for this phenomenon. Preferred nucleation on defect sites, overlapping of zones with reduced supersaturation around growing islands, coalescence of neighboring islands, and growth of larger islands at the expense of smaller ones owing to the Thomson–Gibbs effect (Ostwald ripening) take place most frequently and are most studied [2.66].

Although the preparation of defectless single crystals is already a routine procedure, the complete absence of impurity particles, stacking faults, twin boundaries, emerging points of dislocations, etc. cannot be achieved. It is this presence of defects on the crystal surface which is one of the reasons for the observation of saturation of the nucleus density with time and this was the first to be studied. The defects represents sites on the crystal surface which stimulate nucleation by stronger wetting. Assume for simplicity that they have equal activity (wetting function). Nuclei can form on free active sites whose number is $N_d - N$ with a frequency J'_0 per site, N_d being the total number of active sites. Then the change with time t of the nucleus density reads [2.67]

$$\frac{dN}{dt} = J'_0(N_d - N).$$

Integration subject to the initial condition $N(0) = 0$ results in a simple exponential function

$$N(t) = N_d[1 - \exp(-J'_0 t)],$$

which tends with time to a saturation value equal to N_d . In the more realistic case of a certain activity distribution of the sites, increasing supersaturation will lead to inclusion of less-active sites in the process and increase of the saturation nucleus density [2.68].

Another reason for saturation of the nucleus density is the appearance of *locally undersaturated* zones around growing nuclei where the nucleation rate is reduced or even equal to zero owing to the consumption of the diffusing adatoms [2.69–71]. Sigsbee coined for these zones the term *nucleation exclusion zones* [2.72]. They are also known as *denuded* or *depleted* zones. Nuclei and in turn denuded zones around them are progressively formed and grow during film deposition. When the zones overlap and cover the whole substrate surface the process of nucleation is arrested and saturation of the nucleus density is reached. The radii of the nucleation exclusion zones are defined by the intersection of the gradient of the adatom concentration around the growing island and the critical adatom concentration (or supersaturation) for nucleation to occur (Fig. 2.12). A typical nucleation exclusion zone around a mercury droplet electrodeposited on a platinum single-crystal sphere is shown in Fig. 2.13 [2.73].

The problem of finding the nucleus density when the latter is limited by nucleation exclusion zones has been treated by many authors, such as Kolmogorov, Avrami, and Johnson and Mehl, and solutions for different cases have been found [2.74–78] (for a review see [2.47]). The simultaneous influence of both nucleation exclusion zones and active sites has also been

Fig. 2.12 The definition of nucleation exclusion zones. The radius of the latter is determined by the intersection of the gradient of the supersaturation and the critical supersaturation for noticeable nucleation to occur. Because of the very steep dependence of the nucleation rate on the supersaturation (Fig. 2.7) the nucleation rate inside the zone is assumed equal to zero

addressed [2.79,80]. The problem consists of finding the area $\Theta(t)$ uncovered by depleted zones and thus available for nucleation at a moment t . The number of nuclei is then given by

$$N = J_0 \int_0^t \Theta(\tau) d\tau.$$

The area $1 - \Theta(t)$ represents the sum of all nucleation exclusion zones accounting for the area where neighboring zones have overlapped. The latter is equal to the probability of finding an arbitrary point simultaneously in two or more nucleation exclusion zones [2.74]. Assuming that nuclei are formed on randomly distributed sites with a rate J_0 and that the zones grow with a velocity $v(t) = ck(t)$ the area $\Theta(t)$ is given by [2.74]

$$\Theta(t) = \exp \left(-J_0 \int_0^t S'(t') dt' \right),$$

where

$$S'(t', t) = \pi c^2 \left(\int_{t'}^t k(\tau - t') d\tau \right)^2$$

is the area of a nucleation exclusion zone at a moment t around a nucleus formed at a moment $t' < t$.

Assuming linear growth of the zones ($k(t) = 1$) gives for the nucleus density as a function of time

$$N(t) = J_0 \int_0^t \exp \left(-\frac{\pi}{3} J_0 c^2 t'^3 \right) dt'. \quad (2.51)$$

Fig. 2.13 Nucleation exclusion zone around a mercury droplet electrodeposited on a platinum single-crystal sphere. The droplet is practically invisible. Instead, three light reflections from the illuminating lamp are visible. The mercury droplet has been deposited by applying a short electric pulse followed by a lower overpotential in order to grow it to a predetermined size. Then a high electric pulse is applied to cover the whole surface with mercury with the exception of the area around the droplet (after [2.73])

The saturation nucleus density is obtained under the condition $t \rightarrow \infty$. Integrating (2.51) from zero to infinity gives

$$N_{\text{sat}} \cong 0.9 \left(\frac{J_0}{c} \right)^{2/3}.$$

Another approach was later developed, particularly for nucleation at surfaces, by using a system of kinetic rate equations. It was first introduced by Zinsmeister as a system of equations for the change with time of the concentrations of clusters dN_i/dt ($i = 1, 2, 3, \dots$) for each cluster size, beginning with that of single adatoms [2.81–84]. All birth and death processes were accounted for in dN_i/dt . In addition, the atom arrival rate and re-evaporation were taken into account in the equation of change of the monomers dN_1/dt . In order to solve quantitatively the above system of equations the attachment and detachment frequencies had to be determined. As a result a large amount of papers have been devoted to further elaborating the approach [2.85–92]. In the limit $i^* = 1$ (irreversible aggregation) the

detachment frequencies are equal to zero. The attachment frequencies (capture numbers) were considered by using different approximations, beginning from the mean-field approximation by assuming that the clusters are immersed and grow in a dilute adlayer with an average concentration that does not depend on the location of the clusters, to solutions of diffusion equation around the growing islands in terms of Bessel functions. The system was later greatly simplified by Venables et al. to a system of two equations which were sufficient to illustrate the essential physics [2.93].

We consider first the case of irreversible aggregation. The dimers are assumed to be stable (a third atom joins the dimer before the latter to decay) and immobile. The atoms arrive at the crystal surface, diffuse on it, and collide with each other to produce dimers. Atoms join the dimers and larger clusters upon striking without any obstacle of kinetic origin. This means that the growth of clusters is limited only by the surface diffusion. Coalescence of immobile clusters is ruled out. The detachment frequencies are equal to zero and the capture numbers are omitted for simplicity as they represent figures of the order of unity [2.93]. The system of equations is then reduced to

$$\frac{dN_1}{dt} = F - 2DN_1^2 - DN_1N_s, \quad (2.52a)$$

$$\frac{dN_s}{dt} = DN_1^2, \quad (2.52b)$$

where $F = R/N_0$ is the atom arrival rate in units of number of monolayers, $D = D_s/a^2 = v \exp(-E_{sd}/k_B T)$ is the diffusion (hopping) frequency, and N_s is the sum of all stable clusters

$$N_s = \sum_{i=2}^{\infty} N_i.$$

Single atoms arrive on the surface with frequency F and are consumed by the formation of dimers (the second term on the right-hand side of (2.52a)) and by incorporation into stable clusters (the third term on the right-hand side of (2.52a)). At the very beginning of deposition most of the adatoms are consumed by the formation of dimers. In a later stage of deposition the density of stable clusters increases and the arriving atoms preferentially join stable clusters rather than colliding with each other to produce dimers. Saturation (or very weak dependence on time) is reached and the consumption of atoms by formation of dimers $2DN_1^2$ is practically arrested and becomes negligible compared with the growth term DN_1N_s . A steady state is reached at this stage ($dN_1/dt = 0$) and $N_1 = F/DN_s$.

Substituting the latter into (2.52b) and carrying out the integration gives

$$N_s \propto \left(\frac{D}{F}\right)^{1/3}.$$

This result is easy to generalize for the case of *reversible aggregation*, assuming the critical nucleus consists of $i^* > 1$ atoms. Then one can write a system of two kinetic equations for the single adatoms and the sum of all clusters larger than i^* [2.93]

$$\frac{dN_1}{dt} = F - (i^* + 1)DN_1^{i^*+1} - DN_1N_s, \quad (2.53a)$$

$$\frac{dN_s}{dt} = \omega^* DN_1^{i^*+1}, \quad (2.53b)$$

where $\omega^* = \alpha^* \exp(E^*/k_B T)$ (see (2.50)).

Following the same procedure as above results in

$$N_s \propto \left(\frac{D}{F}\right)^{-\chi}, \quad (2.54)$$

where

$$\chi = \frac{i^*}{i^* + 2} \quad (2.55)$$

is the scaling exponent valid for the case of diffusion-limited nucleation and growth in the absence of any kinetic barrier inhibiting the attachment of atoms to the critical nucleus.

Later Kandel relaxed the condition for diffusion-limited regime of growth, assuming that a barrier exists which inhibits the attachment of atoms to any cluster including the critical nucleus [2.94]. Then the frequency ω^* for collision of atoms with the critical nucleus should contain the term $\exp(-E_b/k_B T)$, where E_b is the barrier concerned. He integrated (2.53b) taking for N_1 a value calculated by the solution of a diffusion equation from the radius R of the nucleus to half of the mean distance $L = 1/\sqrt{\pi N_s}$ between the nuclei and then averaged from R to L . As a result the average adatom concentration included two terms

$$N_1 = A \frac{F}{D} \frac{1}{N_s} + B \frac{F}{D} \frac{1 - \exp(-E_b/k_B T)}{\exp(-E_b/k_B T)} \frac{1}{\sqrt{N_s}},$$

where A and B are constants.

The first term is inversely proportional to N_s as before and does not include the cluster edge barrier E_b . The second term is inversely proportional to the square root of N_s and includes the barrier E_b . Obviously, when $E_b = 0$ the second term is equal to zero and the integration of (2.53b) naturally gives the scaling

exponent (2.55). In the other extreme of significant cluster edge barrier the second term dominates and the integration of (2.53b) gives the same power-law dependence (2.54) but with a scaling exponent

$$\chi = \frac{2i^*}{i^* + 3}, \quad (2.56)$$

which is valid for a kinetic regime of growth.

Equation (2.54) shows a simple power-law dependence of N_s on the ratio D/F of the frequency of surface diffusion to the frequency of atom arrival. While F represents the increase of atoms with time, D introduces the fluxes of disappearance of atoms due either to formation of nuclei or to the further growth of these nuclei. Physically this is the ratio of the flux of consumption of atoms on the crystal surface to the flux of their arrival. A constant ratio D/F means a constant adatom concentration or a constant supersaturation. The increase of D/F can be performed by either increasing the temperature or decreasing the atom arrival rate. The fact that the island density scales with D/F simply means that it depends on the supersaturation. The island density should have one and the same value at a given value of D/F , irrespective of whether it is a result of increasing (decreasing) of temperature or decreasing (increasing) of the atom arrival rate. Increasing D/F means decreasing the supersaturation, which in turn leads to an increase of the nucleus size i^* . Thus, at sufficiently low values of D/F of the order of 10^4 – 10^5 , i^* is expected to be equal to one, whereas at D/F of the order of 10^7 – 10^8 , i^* is expected to be equal to three on a square lattice [2.95]. Assuming a constant atom ar-

rival rate of the order of 10^{-2} monolayers per second, attempt frequency of the order of $1 \times 10^{13} \text{ s}^{-1}$, and a surface diffusion barrier of 0.75 eV an increase of D/F by four orders of magnitude is equivalent to a temperature increase of 200 K.

It should be noted that considering the size of the critical nucleus as an integer above which all clusters are stable is an approximation which strongly simplifies the mathematical treatment of the problem [2.95]. In fact there are never fully stable clusters. Atoms can always detach from them, particularly at high values of D/F or high temperatures. Things look better at low temperatures when bond breaking is strongly inhibited.

The scaling exponent (2.55) varies with i^* from $1/3$ to 1 , whereas (2.56) has values larger than unity already at $i^* > 2$. Thus, one can distinguish between diffusion and kinetic regimes of growth if χ is smaller or greater than unity. Examples of the scaling exponent (2.56) have been reported in surfactant-mediated epitaxial growth: homoepitaxy of Si on Sn-precovered surface of Si(111) [2.96], and of Ge on Pb-precovered surface of Si(111) [2.97]. In the former paper a value of $\chi = 1.76$ has been found from the plot of $\ln N_s$ versus $\ln F$. In the case of homoepitaxial growth of Si(111) under clean conditions a value of $\chi = 0.85$ has been obtained from the same plot of $\ln N$ versus $\ln F$ [2.98]. It could be concluded that the nucleation process takes place either in a diffusion regime with $i^* = 6$ or in a kinetic regime with $i^* = 2$. The latter seems more reasonable, bearing in mind the comparatively low temperature of growth ($< 700 \text{ K}$) and that Si is a very strongly bonded material.

2.5 Second-Layer Nucleation in Homoepitaxy

Growth of defectless low-index crystal surfaces takes place by formation and growth of 2-D nuclei with monolayer height. When the linear size L of the crystal face is small, in fact, smaller than $L_c = (v/J_0)^{1/3}$ [2.99], where v is the rate of lateral growth and J_0 is the nucleation rate, the growth proceeds by a periodic process of formation of a single nucleus followed by its growth to cover completely the crystal face. Thus, perfect layer-by-layer growth takes place.

When the surface area which is in contact with the supersaturated vapor is large, a large amount of nuclei are formed on the crystal surface on one and the same level. During the growth of the first layer nuclei, a certain size Λ can be reached at which second-layer nuclei

can form on top. The average time elapsed from the nucleation of the first-layer nucleus to the appearance of the second-layer nucleus is $\tau = \Lambda/v$. The latter should be inversely proportional to the frequency of nucleation on top of the first-layer nucleus $\bar{J}_0 = J_0 l^2$, or in other words, $\Lambda/v \cong 1/\bar{J}_0$. Thus we find that the critical size for second-layer nucleation is $\Lambda_c = (v/J_0)^{1/3}$ [2.99]. Obviously, when the surface coverage by first-layer nuclei is $\Lambda_c^2 N_s \ll 1$, where N_s is the saturation nucleus density, nuclei of the second, third, etc. layers can form before significant coalescence of the first-layer nuclei takes place. The crystal surface will be rough with many layers growing simultaneously. Multilayer growth takes place. The number N of simultaneously growing layers

depends on v and J_0 . If v is large or J_0 is small, Λ_c will be large and the surface roughness will be small, and vice versa.

In the above physical picture it is assumed that the probabilities of attachment of atoms to a step from both the upper and lower terrace are equal. In other words, it is accepted that the barrier which inhibits the incorporation of the atoms to the step and in turn leads to the kinetic regime discussed above is one and the same from both sides of the step. It was at the beginning of 1966 when Ehrlich and Hudda discovered that the above is completely incorrect [2.100]. They found with the help of field-ion microscopy (the first method which allowed the visualization of single atoms, invented by Erwin Müller in the early 1950s) [2.101], that an atom approaching the step from the upper terrace is repulsed by the step. The additional barrier E_{ES} , known now in the literature as the Ehrlich–Schwoebel barrier, was measured later by Wang and Tsong, who reported values of the order of 0.15–0.2 eV for Re, Ir, and W [2.102]. Much later Wang and Ehrlich reported that the steps attract the atoms approaching them from the lower terrace [2.103]. The same authors observed in the case of Ir(111) that the atoms, instead of being repelled from the descending step, were in fact attracted by it. Thus they found another, *push-out*, mechanism of step-down diffusion in which the second-level atom pushes out the edge atom and occupies the position of the latter rather than making a jump [2.104]. The atoms thus sample the potential profiles shown in Fig. 2.14a in the case of step-down jumping and in Fig. 2.14b in the case of the push-out mechanism.

The physics behind these effects are easy to understand if we compare interlayer diffusion with the same phenomenon on terraces. It is clear that an atom jumping down the step from the upper terrace will be less coordinated from the side of the lower terrace. On the contrary, an atom approaching the step from the lower terrace will be additionally attracted from the atoms belonging to the upper atomic plane. In the case of the push-out mechanism the atoms taking part in the process *respect a fundamental rule of chemistry – minimizing the breaking of bonds* [2.105].

Schwoebel immediately grasped the importance of the discovery of Ehrlich and Hudda and published later in the same year a paper dealing with the effect of the step-down diffusion barrier on the bunching of steps during evaporation [2.106, 107]. He went even further to foresee the push-out mechanism long before Ehrlich observed it experimentally [2.106].

Fig. 2.14a,b Schematic potential diagrams for atoms moving toward ascending and descending steps. **(a)** Traditional view of the Ehrlich–Schwoebel barrier for atoms joining a descending step by a jump and short-range attractive behavior of the ascending step, **(b)** view of the potential sampled by an atom joining a descending step by a push-out mechanism

We consider in this chapter only the traditional Ehrlich–Schwoebel effect of repulsion of atoms from descending steps. The push-out mechanism together with an additional barrier from the lower terrace owing to the presence of surfactant atoms which have decorated the step (the reverse Ehrlich–Schwoebel effect) is considered in [2.108]. The additional ES barrier inhibits the flow of atoms from upper terraces downwards, thus enhancing the nucleation rate on upper terraces. This leads to formation of mounds consisting of concentric two-dimensional islands, one on top of the other, and thus to strong roughening of the surface, a phenomenon which was first predicted by Villain [2.109]. We will consider the same problem as above, defining the critical island size Δ for second-layer nucleation accounting for the ES barrier.

We define Δ in the same way as above but writing it in integral form

$$\int_0^{\Delta} \frac{\bar{J}_0(\rho)}{v(\rho)} d\rho = 1, \quad (2.57)$$

where

$$v(\rho) = \frac{d\rho}{dt} = \frac{R}{2\pi\rho N_s N_0} \quad (2.58)$$

is the rate of growth of the first-layer islands in the case of complete condensation before nuclei on their upper surfaces are formed.

The nucleation frequency \bar{J}_0 is defined as before as

$$\bar{J}_0 = 2\pi \int_0^{\rho} J_0(r, \rho) r dr, \quad (2.59)$$

where J_0 is the nucleation rate as given by (2.50). It is a function of the island's radius ρ through the adatom concentration on the upper surface of the island N_1 . The latter can be determined by solving the diffusion equation (in polar coordinates) in the absence of re-evaporation

$$\frac{d^2 N_1}{dr^2} + \frac{1}{r} \frac{dN_1}{dr} + \frac{R}{D_s} = 0. \quad (2.60)$$

The solution reads

$$N_1 = A - \frac{R}{4D_s} r^2, \quad (2.61)$$

where the integration constant should be determined by the boundary condition

$$j = -D_s \left(\frac{dN_1(r)}{dr} \right)_{r=\rho}, \quad (2.62)$$

where $j = j_+ - j_-$ is the net flux of atoms to the descending step which encloses the island, j_+ and j_- being the attachment and detachment fluxes.

Bearing in mind Fig. 2.14 j_+ and j_- read

$$j_+ = av N_{st} \exp\left(-\frac{E_{sd} + E_{ES}}{k_B T}\right),$$

$$j_- = av N_k \exp\left(-\frac{\Delta W + E_{sd} + E_{ES}}{k_B T}\right),$$

where N_{st} is the adatom concentration in the vicinity of the step, v is the attempt frequency, N_k is the concentration of atoms in a position (presumably kink position) for easy detachment from the step, and $\Delta W = \varphi_{1/2} - E_{des}$ is the energy to transfer an atom from a kink position onto the terrace.

The total flux j then reads

$$j = av(N_{st} - N_1^e) \exp\left(-\frac{E_{sd}}{k_B T}\right) \frac{1}{S}, \quad (2.63)$$

where $S = \exp(E_{ES}/k_B T)$, and $N_1^e = N_k \exp(-\Delta W/k_B T)$ is the equilibrium adatom concentration (see (2.12)).

Combining (2.62) and (2.63) and bearing in mind that $N_{st} = A - R\rho^2/4D_s$ yields [2.110]

$$N_1 = N_1^e + \frac{R}{4D_s} (\rho^2 + 2\rho a S - r^2). \quad (2.64)$$

As seen in the case of negligible ES barrier ($2aS/\rho \ll 1$), (2.64) turns into

$$N_1 = N_1^e + \frac{R}{4D_s} (\rho^2 - r^2). \quad (2.65)$$

The adatom concentration on top of the island surface has a profile of a dome with a maximum above the island's center ($r = 0$) and reaches its equilibrium value N_1^e near the island's edge ($r = \rho$). It follows that second-layer nucleation is favored around the middle of the island.

In the other extreme ($2aS/\rho \gg 1$) we neglect the difference $\rho^2 - r^2$ and obtain

$$N_1 \approx \frac{R}{2D_s} \rho a S.$$

This means that the adatom population on top of an island with repelling boundaries is uniformly distributed all over the surface of the island and a nucleation event can occur with equal probability at any point of it.

We substitute (2.64) into (2.50) and the latter into (2.59) to obtain after integration [2.110]

$$\bar{J}_0 = A[(\rho^2 + 2\rho a S)^{i^*+2} - (2\rho a S)^{i^*+2}], \quad (2.66)$$

where

$$A = \frac{\pi\alpha^*}{(i^*+2)} D_s N_0^2 \exp\left(\frac{E^*}{k_B T}\right) \left(\frac{R}{4D_s N_0}\right)^{i^*+1}.$$

As seen, a negligible ES barrier ($2aS \ll \rho$) turns (2.66) into

$$\bar{J}_0 = A \rho_1^{2(i^*+2)}. \quad (2.67)$$

The condition for layer-by-layer growth (formation of one nucleus for the time $T = R/N_0$ of deposition of a complete monolayer)

$$N = \int_0^T \bar{J}_0(\rho_1) dt = 1 \quad (2.68)$$

gives for the number of the growth pyramids the expression [2.111] (for a review see [2.21])

$$N_s = \frac{1}{4\pi} C^* N_0 \left(\frac{D}{F}\right)^{-\chi} \exp\left(\frac{E_{i^*}}{(i^*+2)k_B T}\right), \quad (2.69)$$

where C^* is a very weak function of i^* of the order of unity. The above equation is in fact (2.54) with the familiar scaling exponent (2.55).

In the other extreme ($2aS \gg \rho$) we take the last two terms of the expansion of the sum in (2.66) and the latter turns into

$$\bar{J}_0 = B \rho^{i^*+3}, \quad (2.70)$$

where

$$B = \pi\alpha^* D_s N_0^2 \exp\left(\frac{E^*}{k_B T}\right) \left(\frac{RaS}{2D_s N_0}\right)^{i^*+1}.$$

Following the above procedure gives for this case [2.112]

$$N_s = \frac{1}{\pi} C^* N_0 \left(\frac{D}{F}\right)^{-\chi} \exp\left(\frac{2[E_{i^*} + (i^*+1)E_b]}{(i^*+3)k_B T}\right), \quad (2.71)$$

where C^* is another very weak function of i^* of the order of unity. We again obtained (2.54) but the scaling exponent is given by (2.56).

We can now calculate the critical radii of the islands for second-layer nucleation in both cases of low (subscript “0”) and high (subscript “ES”) Ehrlich–Schwoebel barrier. Substituting (2.67), (2.70) and (2.58) into (2.57) gives after integration [2.110]

$$\Lambda_0 = aC_0 \left(\frac{D}{F}\right)^{i^*/2(i^*+3)}, \quad (2.72)$$

with

$$C_0 \cong \left(\frac{N_0 e^{-E^*/k_B T}}{\alpha^* N_s}\right)^{1/2(i^*+3)}, \quad (2.73)$$

for the case of negligible ES barrier, and

$$\Lambda_{ES} = aC_{ES} \left(\frac{D}{F}\right)^{i^*/(i^*+5)} S^{-(i^*+1)/(i^*+5)}, \quad (2.74)$$

with

$$C_{ES} \cong \left(\frac{N_0 e^{-E^*/k_B T}}{\alpha^* N_s}\right)^{1/(i^*+5)}, \quad (2.75)$$

for the other limiting case of a significant ES barrier.

Let us compare N_s and Λ in both cases. For this purpose we take typical values for the quantities involved: $N_0 = 1 \times 10^{15} \text{ cm}^{-2}$, $R = 1 \times 10^{13} \text{ cm}^{-2} \text{ s}^{-1}$, $F = R/N_0 = 1 \times 10^{-2} \text{ s}^{-1}$, $E_{sd} = 0.4 \text{ eV}$, $E_{ES} = 0.2 \text{ eV}$, $T = 400 \text{ K}$, $i^* = 1$, and $E^* = 0$. Then, in the case of $E_{ES} = 0$, $N_s \approx 6 \times 10^{10} \text{ cm}^{-2}$ and $\Lambda_0 \approx 180 \text{ \AA}$. In the other extreme, $N_s \approx 1 \times 10^{12} \text{ cm}^{-2}$ and $\Lambda_{ES} \approx 50 \text{ \AA}$ is 3 times smaller. We conclude that with a significant ES barrier a larger density of islands is formed which have much smaller critical size for second-layer nucleation. Mounding rather than planar growth is expected.

It is of interest to check the above theory. For this purpose we calculate the number n of atoms on the surface of the base island when its radius has just reached the critical value Λ . We integrate the adatom concentration (2.64) on the island's surface

$$n = 2\pi \int_0^\Lambda n_s(r, \Lambda) r dr$$

and find

$$n = \frac{\pi F}{8D} N_0^2 \Lambda^4 \left(1 + \frac{4aS}{\Lambda}\right).$$

We will consider as examples two surfaces of fcc crystals: (100) and (111). The reason is that the (100) surfaces are characterized by a large terrace diffusion barrier and a small step-edge barrier. This is the reason why, during growth, (100) surfaces demonstrate as a rule oscillations of the intensity of the specular beam, which are an indication of layer-by-layer growth. On the contrary, the smoother (111) surfaces are characterized with small intralayer diffusion barriers and large interlayer barriers. The result is a roughening of the crystal surface from the very beginning of deposition and a monotonous decrease of the intensity of the specular beam [2.112].

We consider first the case of Cu(001) [2.113]. The authors have measured the step kinetics of a pyramid consisting of 2-D islands, one on top of the other, and determined the critical radius $\Lambda \approx 3 \times 10^{-5}$ cm of the uppermost island at which the next layer nucleus is formed ($T = 400$ K, $F = 0.0075$ s $^{-1}$, $E_{sd} = 0.4$ eV, $a = 2.55 \times 10^{-8}$ cm, $N_0 = 1.53 \times 10^{15}$ cm $^{-2}$). Comparison with the theory produced the value $E_{ES} = 0.125$ eV. Then, by using the above formula we find for the number of atoms which gives rise to the new monolayer nucleus the value $n = 70$. Note that $aS/\Lambda \approx 0.03$, which confirms the above statement that the kinetics at fcc(001) surfaces is not dominated by the interlayer diffusion and the profile of the adatom concentration looks like a dome.

We consider next the case of Pt(111) [2.114]. Bott, Hohage, and Comsa observed by scanning tunneling microscopy (STM) the appearance of second-layer nuclei at surface coverages of 0.3 (425 K, $N_s = 3.37 \times 10^{10}$ cm $^{-2}$) and 0.8 (628 K, $N_s = 3.5 \times 10^9$ cm $^{-2}$) ($R = 5 \times 10^{12}$ cm $^{-2}$ s $^{-1}$). The activation energy for terrace diffusion is well known to be 0.25–0.26 eV [2.115, 116]. Values for E_{ES} varying from 0.12 eV (see [2.117]) to 0.44 eV have been estimated [2.118]. The average number of atoms on the island's surface as computed with the help of the above equation for n turned out to be of the order of 1×10^{-2} , i. e., much less than unity, which is unphysical. In fact n becomes greater than unity when $E_{ES} > 0.5$ eV, which means that the atoms at the island's periphery must overcome a total barrier of about 0.75 eV, which is too large to be believed. In contrast to the previous case, however, $aS/\Lambda \gg 1$, which means that it is interlayer diffusion that dominates the kinetics, and the adatom population on top of the island is spatially uniform.

Whereas the Cu(001) case is physically reasonable, the (111) case looks puzzling. In order to solve the problem of the high ES barrier Krug et al. accounted for the probabilistic nature of the main processes involved [2.117]. The authors have taken into account the fact that the atoms arrive randomly on the island's surface with an area $\pi\rho^2$ but not at equal intervals $\Delta t = 1/\pi\rho^2 R$ as is implicitly assumed in the model described above. Second, the time τ that the atoms reside on the island before rolling over and joining the descending edge is also a random quantity. The latter is directly proportional to the island's periphery $2\pi\rho$ and inversely proportional to the rate of step-down diffusion $\omega = av \exp[-(E_{sd} + E_{ES})/k_B T]$, i. e., $\tau \approx 2\pi\rho/\omega = 2\pi\rho aS/D_s$. We introduce further the time $\tau_{tr} = \pi\rho^2/D_s$ required for an atom to visit all sites of

the island. The condition $\tau/\tau_{tr} \gg 1$ is equivalent to $2aS/\rho \gg 1$, which is in fact the condition for nucleation kinetics dominated by step-down diffusion (see (2.70)). Assuming $i^* = 1$ (the dimers are stable and immobile) it is concluded that, as soon as two atoms are present simultaneously on the island's surface, their encounter is inevitable. Thus the necessary and sufficient condition for the atoms to meet each other and give rise to a stable cluster is $\tau_{tr} \ll \tau$. Then the probability of nucleation p_{nuc} is equal to the probability p_2 for two adatoms to be present simultaneously on the island. p_2 is determined by the condition that the time of arrival t_2 of the second atom be shorter than the time t_1 of departure of the first atom. Assuming that t_1 and t_2 are randomly distributed around the average values τ and Δt , respectively, one obtains after integration

$$p_{nuc} = \frac{1}{\tau \Delta t} \int_0^\infty dt_1 e^{-t_1/\tau} \int_0^{t_1} dt_2 e^{-t_2/\Delta t} = \frac{\tau}{\tau + \Delta t}.$$

Two limiting cases are possible. The case $\tau \gg \Delta t$ and $p_{nuc} \approx 1$ is trivial; it means that the ES barrier is infinitely high and there will always be at least one atom on top of the island. The physically interesting case is when $\Delta t \gg \tau$ and $p_{nuc} = \tau/\Delta t$. Then the nucleation frequency $\bar{J}_0 = \pi\rho^2 R p_{nuc}$ reads

$$\bar{J}_0 \propto \frac{aR^2\rho^5 S}{D_s}. \quad (2.76)$$

This equation should be compared with (2.70). With $i^* = 1$ the latter gives

$$\bar{J}_0 \propto \frac{a^2 R^2 \rho^4 S^2}{D_s}. \quad (2.77)$$

Comparing both formulae shows that the mean-field expression (2.77) is $aS/\rho \gg 1$ times larger than the probabilistic one (2.76). The explanation is simple. Equation (2.77) is based on the implicit assumption that on top of the island there is a time-averaged number (smaller than unity but constant) of atoms all the time. As shown above this is indicative of a large ES barrier whose mathematical expression is just $aS/\rho \gg 1$. In fact the island's surface is empty most of the time and is sometimes populated by a single atom, and it very rarely happens that during this time a second atom arrives. Once two atoms are simultaneously present on the island a nucleus is formed with a probability close to unity. That is why the authors coined for this model the term *the lonely adatom model*. The problem of second-layer nucleation has been intensively studied [2.119, 120]. It has been found that the mean-field

approach is applicable for critical nuclei consisting of more than three atoms. If this is not the case ($i^* = 1, 2$),

the random character of the processes involved becomes significant.

2.6 Mechanism of Clustering in Heteroepitaxy

Fig. 2.15 Plot of the binding energy per atom in units of the energy of a single first-neighbor bond ψ of monolayer, bilayer, and trilayer islands with simple cubic lattice as a function of the total number of atoms. The wetting parameter $\phi = 0.1$ (after [2.35]) ►

We consider first the growth of a heteroepitaxial thin film by the mechanism of Volmer–Weber. As the wetting is incomplete the thermodynamics requires 3-D islanding directly on top of the substrate. We study the stability of islands with different thickness beginning from one monolayer against their volume (or total number of atoms). In other words we study the behavior of the binding energy $-U_i$ in (2.27), which is equal to the surface energy term Φ up to a constant $i\phi_{1/2}$ [2.35].

We study for simplicity a Kossel crystal with (100) substrate orientation. The same result is obtained by using any other lattice and substrate orientation [2.35]. As a first approximation we omit the effect of the lattice misfit. As discussed above the strain energy makes as a rule a minor contribution with the same sign to the difference of the cohesive ψ and adhesive ψ' energies. As another approximation we consider our crystal in a *continuous* way, assuming that the shape remains a complete square irrespective of the number of atoms in it. We calculate first the binding energies of monolayer, bilayer, and trilayer islands with a square shape of the base and consisting of a total of N atoms. Restricting ourselves to nearest-neighbor bonds the energies read

$$\begin{aligned}\frac{U_1}{N\psi} &= -3 + \phi + \frac{2}{\sqrt{N}}, \\ \frac{U_2}{N\psi} &= -3 + \frac{\phi}{2} + \frac{2\sqrt{2}}{\sqrt{N}}, \\ \frac{U_3}{N\psi} &= -3 + \frac{\phi}{3} + \frac{2\sqrt{3}}{\sqrt{N}},\end{aligned}$$

where ϕ is the wetting function (2.18).

Fig. 2.16 Schematic process for the evaluation of the activation energy of the mono–bilayer transformation. The initial state is a square monolayer island with n_0 atoms in the edge. The intermediate state is a monolayer island with n atoms in the edge plus a second level island with n' atoms in the edge so that $n^2 + n'^2 = n_0^2$. The final state is a complete bilayer island ►

We plot the above energies as a function of N and find that monolayer-high islands are stable against

Fig. 2.17 The energy change which accompanies the mono–bilayer transformation in Volmer–Weber growth (after [2.35])

Fig. 2.18 Mono–bilayer transformation curve in Stranski–Krastanov growth representing the energy change in units of bond energy as a function of the number of atoms in the upper level. The lattice misfit is 2.5% (after [2.122])

bilayer islands up to a critical size denoted by N_{12} (Fig. 2.15). The bilayer islands are stable from this size up to a second critical size N_{23} , beyond which tri-

layer islands become stable, etc. These critical sizes are inversely proportional to the square of the wetting function and go to infinity when $\phi \rightarrow 0$. The latter means that, at $\phi = 0$, 3-D islands will not be able to form. Instead, layer-by-layer growth is expected according to the thermodynamics at complete wetting. At finite values of ϕ a mono–bilayer transformation should take place when $N > N_{12}$. A bi–trilayer transformation is expected to occur when $N > N_{23}$, etc. It is very important to note that *monolayer-high islands appear as necessary precursors for 3-D islands* [2.121].

We study further the mechanism of transformation of monolayer to bilayer islands, assuming the following imaginary process illustrated in Fig. 2.16 [2.35]. Atoms detach from the edges of the monolayer islands, which are larger than N_{12} and thus unstable against bilayer islands, diffuse on top of them, aggregate, and give rise to second-layer nuclei. The latter grow further at the expense of the atoms detached from the edges of the lower islands. The process continues up to the moment when the upper island completely covers the lower-level island. The energy change associated with the process of transformation at a particular stage is given by the difference between the energy of the incomplete bilayer island and that of the initial monolayer island

$$\frac{\Delta U_{12}(n')}{\psi} = -n^2\phi - \frac{n'^2}{n_0} + 2n', \quad (2.78)$$

where the approximation $n_0 + n = 2n_0$ is used in the beginning of the transformation, n_0 , n , and n' being the numbers of atoms in the edge of the initial monolayer island, in the lower edge of the incomplete bilayer island, and in the edge of the second-layer island, respectively (Fig. 2.16).

Equation (2.78) is plotted in Fig. 2.17. As seen, it displays a maximum at some critical size

$$n'^* = \frac{n_0}{1 + n_0\phi}. \quad (2.79)$$

The height of the maximum is given by

$$\Delta U_{12}^* = \frac{n_0}{1 + n_0\phi} \psi = n'^* \psi, \quad (2.80)$$

as should be expected by the classical consideration of the nucleation process (2.36). It follows that the mono–bilayer transformation is a nucleation process.

The same physics functions in the clustering during the Stranski–Krastanov growth of thin films beyond the wetting layer [2.122]. The Stranski–Krastanov growth represents a growth of A on strained A. The strained wetting layer of A is formed on the surface of another

crystal B with different lattice parameter. The 3-D islands which form on the wetting layer are fully strained in the middle but relaxed at the side-walls and edges. The atoms near the edges of the base are displaced from the positions they should occupy if the islands were completely strained to fit the wetting layer. As a result the adhesion of the atoms near the edges of the base to the substrate (the wetting layer) is weaker compared with the atoms in the middle of the island's base. Therefore, the average wetting is incomplete, $0 < \phi < 1$, which is the thermodynamic condition for clustering. The detachment of atoms from the edges and the formation of a cluster in the second level beyond some critical size is energetically favorable. The numerically calculated energy accompanying this process is shown in Fig. 2.18 [2.122]. The atoms interact through a pair potential of Morse type whose anharmonicity can be varied by adjusting two constants that govern separately the repulsive and attractive branches, respectively [2.123, 124]. The 3-D crystallites have fcc lattice and (100) surface orientation, thus possessing the shape of a truncated square pyramid. As seen, a critical nucleus consisting of three atoms is formed, beyond which the energy goes down as in an ordinary nucleation process. The misfit dependence of the critical size N_{12} , the nucleus size, and the work for nucleus formation are shown in Fig. 2.19 [2.122]. The nucleation character of the transformation is clearly observed. The energy barrier and the number of atoms in the cluster with highest energy increase steeply with decreasing lattice misfit, which in this case plays the role of the

Fig. 2.19 Misfit dependence of the critical size N_{12} , the critical nucleus size (both expressed in number of atoms), and the nucleation barrier (in units of ψ) for compressed overlayers. The initial size of the monolayer island is 20×20 atoms (after [2.122])

supersaturation. The number N_{12} also goes to infinity, illustrating the critical behavior of the transition from monolayer (2-D) to bilayer (3-D) islands.

It should be pointed out that the mono-bilayer transformation of islands under tensile stress does not display a nucleation behavior, particularly at lower absolute values of the misfit. However, this problem is outside the scope of the present review and will not be discussed.

2.7 Effect of Surfactants on Nucleation

It was found long ago that very often epitaxial films grow in a layer-by-layer mode and show better quality when the vacuum is poor [2.125, 126]. Much later *Steigerwald* et al. found that intentionally adsorbed oxygen on Cu(001) suppresses agglomeration and interdiffusion upon deposition of Fe [2.127]. The significance of these observations was immediately grasped and the very next year *Copel* et al. reported that preadsorption of As drastically alters the mode of growth of Ge on Si(001) and of Si on Ge(001) by suppressing the clustering in the Stranski–Krastanov and Volmer–Weber modes of growth, respectively [2.128]. They suggested an interpretation of their observations in terms of the change of the wetting of the substrate by the overlayer due to the effect of the third element and

used the term *surfactant* to stress the thermodynamic nature of the phenomenon. Intensive studies and heated debate concerning the effect of the third elements on the thermodynamics and kinetics of the processes followed. It was shown that the surfactants change not only the thermodynamics but also the kinetics of the processes involved [2.5, 129]. Nevertheless, the term surfactant was widely accepted in the literature. We explore here the effect of surfactants on nucleation in the simpler case of homoepitaxy. Accounting for the unlike substrate requires only the inclusion of a term containing the wetting function (2.19) into the work of nucleus formation.

We calculate first the work for nucleus formation by using the following imaginary process

Fig. 2.20a–c Calculation of the Gibbs free energy change for nucleus formation on a surfactant-precovered surface. **(a)** The initial surface covered with a complete monolayer of surfactant atoms denoted by *filled circles*; **(b)** the surfactant layer is evaporated and a cluster consisting of i atoms is created; **(c)** the surfactant layer is condensed back and a cluster consisting of i surfactant atoms is formed on top (after [2.130])

(Fig. 2.20) [2.130]. In order to illustrate the essential physics for simplicity we first make use of the classical nucleation theory. The initial state is a surface of the crystal (C) covered by a complete monolayer of surfactant (S) atoms. We first evaporate reversibly and isothermally all S atoms. Then on the clean surface we produce a cluster consisting of i C atoms. Assuming a square shape with edge length l the work for cluster formation in absence of a surfactant reads

$$\Delta G_0 = -i\Delta\mu + 4l\kappa_c,$$

where κ_c is the specific edge energy.

We condense back the S atoms. We gain energy $-4ls\kappa_c$ due to saturation of the dangling bonds at the cluster periphery by the S atoms, and spend energy $4l\kappa_s$ to create the new step which surrounds the cluster con-

sisting of S atoms. The work for nucleus formation then reads [2.130]

$$\Delta G_s = \Delta G_0 - 4ls\kappa_c + 4l\kappa_s, \quad (2.81)$$

where κ_s is the specific edge energy of the S cluster and the parameter

$$s = 1 - \frac{\omega}{\omega_0}$$

accounts for the saturation of the dangling bonds by S atoms. It is a measure of the *surfactant efficiency*, as the quantities

$$\omega = \frac{1}{2}(\psi_{cc} + \psi_{ss}) - \psi_{sc} \quad (2.82)$$

and

$$\omega_0 = \frac{1}{2}\psi_{cc}$$

are the energies of the S-saturated and unsaturated dangling bonds, respectively. The subscripts “cc,” “ss,” and “sc” denote the bond energies C–C, S–S, and S–C, respectively.

Looking at (2.82) it becomes clear that it in fact represents the energetic parameter that determines the enthalpy of mixing of the two species C and S. It must be positive in order to allow the segregation of the surfactant. In the absence of a surfactant $\psi_{ss} = \psi_{sc} = 0$, $\omega = \omega_0$, and $s = 0$. In the other extreme, $\psi_{ss} + \psi_{cc} = 2\psi_{sc}$ and $s = 1$. Thus the parameter s varies from 0 at complete inefficiency to 1 at complete efficiency. (In general the parameter s can be greater than unity, which means $\omega < 0$. However, this means an alloying of the surfactant with the growing crystal, which will have deleterious consequences for the quality of the overlayer and should be avoided.)

It follows from (2.81) that, in the case of surfactant-mediated growth, the Gibbs free energy for nucleus formation contains two more terms that have opposite signs and thus compete with each other. The s -containing term accounts for the decrease of the edge energy of the cluster owing to the saturation of the dangling bonds by the surfactant atoms. The energy $4l\kappa_s$ of the dangling bonds of the periphery of the cluster, consisting of S atoms, which is unavoidably formed on top of the 2-D nucleus due to the segregation of the surfactant, increases the work of cluster formation.

Finding a solution for a small number of atoms in the critical nucleus in the atomistic extreme is straightforward. We make use of (2.27)

$$\Phi = i\phi_{1/2} - U_i$$

Fig. 2.21 Change of the Gibbs free energy for cluster formation relative to the work needed to disjoin two C atoms versus the number of atoms on the (111) surface of a fcc crystal. The value of the surfactant efficiency s is denoted by figures on each curve. The structure of the nucleus is given by the filled circles. The gray circles denote the atoms that turn the critical nuclei into smallest stable clusters (after [2.130])

for the edge energy of both clusters instead of using the capillary term for the edge energy κ .

The binding energy U_i can be divided into lateral energy E_i and desorption energy E_{des} (assuming additivity of the bond energies)

$$U_i = E_i + iE_{\text{des}},$$

and for Φ one obtains

$$\Phi = i\Delta W - E_i,$$

where $\Delta W = \varphi_{1/2} - E_{\text{des}}$ is the energy to transfer an atom from a kink position onto the terrace.

We then substitute Φ for $4l\kappa_c$ in (2.81) to obtain

$$\Delta G_s(i) = -i\Delta\mu + i(1-s)\Delta W - (1-s)E_i + \Phi_s, \quad (2.83)$$

where Φ_s has the meaning of the edge energy $4l\kappa_s$ of the surfactant cluster.

Figure 2.21 shows the dependence of $\Delta G_s(i)$ in units of the crystal bond strength, ψ_{cc} , on the cluster size i for the (111) surface of fcc metals ($\varphi_{1/2} = 6\psi_{cc}$,

$E_{\text{des}} = 3\psi_{cc}$, $\Delta W = 3\psi_{cc}$), with $\psi_{ss}/\psi_{cc} = 0.2$, constant supersaturation $\Delta\mu = 1.1\psi_{cc}$, and different values of s denoted by figures on each curve. As seen, $\Delta G_s(i)$ represents a broken line (as should be expected for a small number of atoms, cf. Fig. 2.10), displaying a maximum at $i = i^*$. Under clean conditions ($s = 0$) the critical nucleus consists of two atoms. When s is very small ($= 0.05$, the surfactant is almost inefficient), the number of atoms in the critical nucleus equals six due to the contribution of the edge energy of the surfactant cluster $4l\kappa_s$. The work of formation of the critical nucleus also increases. Increasing s to 0.3 due to decrease of the edge energy of the cluster leads to a decrease of the nucleation work and i^* becomes again equal to two. At some greater value of s ($= 0.7$), $i^* = 1$ and the aggregation becomes irreversible.

We see that the critical nucleus size differs under one and the same conditions (temperature, rate of deposition) in the absence and presence of a surfactant. In general, we should expect a decrease of the nucleus work and, in turn, a steep increase of the nucleation rate. As a result a larger density of smaller 2-D islands will form. The latter can coalesce and cover completely the surface before formation of nuclei of the upper layer. Thus surfactants can induce layer-by-layer growth by enhancing the nucleation rate [2.131, 132].

The rate of nucleation reads (see (2.42))

$$J_s = \omega_s^* \Gamma N_0 \exp\left(-\frac{\Delta G_s(i^*)}{k_B T}\right), \quad (2.84)$$

where ω_s^* is the flux of atoms to the critical nucleus in the presence of a surfactant, and $\Gamma \cong 1$ is the Zeldovich factor. $\Delta G_s(i^*)$ is given by (2.83) with $i = i^*$.

Bearing in mind that $\Delta\mu = k_B T \ln(N_1/N_1^e)$, where N_1 and N_1^e are the real and the equilibrium adatom concentrations, we can write

$$\Delta\mu = k_B T \ln\left(\frac{N_1}{N_0}\right) - k_B T \ln\left(\frac{N_1^e}{N_0}\right), \quad (2.85)$$

where N_1^e is given by (2.12).

Combining (2.83–2.85) and (2.12) gives

$$J_s = \omega_s^* \Gamma N_0 \left(\frac{N_1}{N_0}\right)^{i^*} \times \exp\left(\frac{i^* s \Delta W + (1-s)E^* - \Phi_s}{k_B T}\right). \quad (2.86)$$

In the absence of a surfactant, $s = 0$, we obtain the familiar expression (2.50) bearing in mind that $\omega_s^* = \omega^* = \alpha^* D_s N_1$.

Note that the presence of the surfactant is not accounted for only by the s -containing terms in the exponential. It is the flux ω_s^* that strongly depends on the mechanism of transport of crystal atoms to the critical nucleus [2.133, 134]. In the case when the transport of atoms to the critical nucleus takes place under the condition of reversible exchange/deexchange of S and C atoms (the time of de-exchange is much smaller than the time of deposition of complete monolayer and atoms have time to perform many exchange/de-exchange events) the nucleus density is given by [2.134] (see for more details [2.21])

$$N_S = N_{s,0} \exp\left(-\frac{\chi}{i^*} \frac{E_S}{k_B T}\right), \quad (2.87)$$

where $N_{s,0}$ and χ are given by (2.71) and (2.56), and E_S combines all energy contributions that depend on the presence of the surfactant. Within the framework of the classical nucleation theory the latter is given by

$$E_S = -4ls\kappa_c + 4l\kappa_s + E_{ex}^* - i^*[(E_{dex} - E_{ex}) - (E_{sd}^0 - E_{sd})], \quad (2.88)$$

where E_{ex} and E_{dex} are the barriers for exchange and de-exchange far from growing nuclei, E_{ex}^* is the barrier for exchange at the edge of the critical nucleus, and E_{sd}^0 and E_{sd} are the barriers for diffusion on clean surface and on top of the surface of the surfactant monolayer. As seen, the first two terms in E_S are of thermodynamic origin whereas the last two terms are of purely kinetic origin.

It follows that the exponential multiplying $N_{s,0}$ can be smaller or larger than unity depending on the sign of E_S . The latter in turn depends on the interplay of the energies involved. We consider in more detail the case of

Sb-mediated growth of Si(111) [2.98, 135]. For this case *Kandel* and *Kaxiras* computed the values $E_{dex} = 1.6$ eV, $E_{ex} = 0.8$ eV, and $E_{sd} = 0.5$ eV [2.136]. The value of $E_{sd}^0 = 0.75$ eV has been calculated from experimental data by *Voigtländer* et al. [2.98]. Thus a value of 0.55 eV was found for the difference $(E_{dex} - E_{ex}) - (E_{sd}^0 - E_{sd})$. We recall that $-4ls\kappa_c = sE^* - i^*s\Delta W$, where ΔW is of order of the half of the heat of evaporation, which for Si is equal to 4.72 eV [2.137]. It can be shown by inspection that $i^*\Delta W$ is always larger than E^* . Thus, when $i^* = 1$, $E^* = 0$ and $\Delta W \cong 2.3$ eV, and when $i^* = 2$, $E^* = 2.3$ eV and $i^*\Delta W \cong 4.6$ eV, etc. The value of s is close to unity as evaluated from the surface energies of Sb and Si available in the literature. It is thus concluded that it is the decrease of the edge energy of the nuclei $4ls\kappa_c$ due to the saturation of the dangling bonds with S atoms which plays the major role and determines the sign of E_S [2.21]. The latter explains the larger density of 2-D nuclei in surfactant-mediated growth of Si(111) compared with growth in clean conditions [2.98].

Kandel and *Kaxiras* assumed that the exchange/de-exchange processes influence the kinetics of nucleation by affecting the diffusivity of the atoms and derived an expression for an effective diffusion coefficient including the respective barriers [2.5]

$$D_{eff} \cong D_s^0 \exp\left(-\frac{(E_{dex} - E_{ex}) - (E_{sd}^0 - E_{sd})}{k_B T}\right),$$

and concluded that the atom diffusivity is inhibited due to $(E_{dex} - E_{ex}) > (E_{sd}^0 - E_{sd})$, which leads to increase of the nucleus density according to the scaling relation (2.54). As discussed above the more rigorous analysis shows that it is the thermodynamic term in (2.88) that controls the effect of the surfactant rather than the kinetic barriers.

2.8 Conclusions and Outlook

As shown above the nuclei of the new phase, particularly on surfaces, represent small clusters whose structure, shape, energy, and even size are still unclear. A large amount of work remains to be done

in order to study the stability of small clusters of materials with different chemical bonds and crystal lattices as a function of their structure, shape, and size.

3. Morphology of Crystals Grown from Solutions

Francesco Abbona, Dino Aquilano

Growth from solutions is widely used both in research laboratories and in many industrial fields. The control of crystal habit is a key point in solution growth as crystals may exhibit very different shapes according to the experimental conditions. In this chapter a concise review is given on this topic. First, the equilibrium shape is rather deeply developed due to its primary importance to understand crystal morphology, then the growth shape is treated and the main factors affecting the crystal habit are briefly illustrated and discussed. A rich literature completes the chapter.

Growth from solutions is widely used both in research laboratories and in many industrial fields. The control of crystal habit is a key point in solution growth as crystals may exhibit very different shapes according to the experimental conditions. In this chapter a concise review is given on this topic. First, the equilibrium shape is rather deeply developed due to its primary importance to understand crystal morphology, then the growth shape is treated and the main factors affecting the crystal habit are briefly illustrated and discussed. Interest in the crystal habit of minerals dates back a long time in the history of mankind. A detailed history on this topics and crystallization in general is given by *Scheel* [3.1]; here only a short account of crystal morphology is presented. Crystal habit, which attracted the interest of great scientists such as Kepler, Descartes, Hooke, and Huygens, is relevant from the scientific point of view, since it marks the beginning of crystallography as a science. Its birth can be dated to 1669 when the Danish scientist Niels Steensen, studying in Florence the quartz and hematite crystals from Elba island, suggested the first law of crystallography (constancy of the dihedral angle) and the mechanism of face growth (layer by layer). A century later this law was confirmed by Romé de l'Isle. At the end of the 18th century the study of calcite crystals led the French abbé René Just Haüy to enunciate the first theory on crystal structure and to discover the second law (rational indices). It is worth noticing that these early scholars met with great difficulty in studying crystal habit since, contrary to botany and zoology where each species has its own definite morphology, the crystal habit of minerals is strongly variable within the same species. In the first part of the 19th century the study of crystal habit led to the development of the concept of symmetry and the derivation of the 32 crystal classes. Bravais, by introducing the idea of the crystal lattice, was the first to try to relate crystal habit to internal structure (the Bravais law, saying that the crystal faces are lattice planes of high point density). At the end of the 19th century research on internal symmetry ended with the derivation of the 230 space groups. In this century research on crystallization, mainly from solution but also from melt, went on and interlaced with progress in other disciplines (chemistry, physics, thermodynamics, etc.). We should recall the important contributions by Gibbs (1878), Curie (1885), and Wulff (1901) on the equilibrium form of crystals, which was tackled later from an atomistic point of view by *Stranski* [3.2] and *Stranski* and *Kaischew* [3.3,4].

The relationship between morphology and internal structure (the Bravais law) was treated by *Niggli* [3.5] and developed by *Donnay* and *Harker* [3.6], who considered the space group instead of the Bravais lattice type as a factor conditioning the crystal morphology. From about 1950 onwards, interest in crystal growth in-

creased due to the role of crystals in all kinds of industry and the discovery of relevant properties of new crystalline compounds. Besides the technological progress, a milestone was the publication in 1951 of the first theory on growth mechanisms of flat crystal faces by *Burton*, *Cabrera*, and *Frank* (BCF) [3.7].

Also, the crystal habit was receiving growing attention due to theoretical interest and industrial needs. The Donnay–Harker principle is exclusively crystallographic. A chemical approach was adopted by Hartman and Perdok; looking at crystal structure as a network of periodic bond chains (PBC) they published in 1955 a method that is still fundamental to studies of theoretical crystal morphology [3.8–10]. The method, at first qualitative, was made quantitative through the calculation of the broken bond energy and, since about 1980, has been integrated with the statistical mechanical theory of Ising models which led to the integrated Hartman–Perdok roughening transition theory [3.11], later applied to modulated crystals [3.12]. These methods do not take into account the external habit-controlling factors, namely the effects of fluid composition and supersaturation, which are explicitly considered in the interfacial structure (IS) analysis [3.13]. An improvement in predicting morphology was represented by the application of ab initio calculations to the intermolecular interactions between tailor-made additives and crystal surface [3.14].

Computer facilities have promoted tremendous advances in all kinds of calculation necessary in the different sectors of crystal growth, enabling progress in theoretical approaches and sophisticated simulations which are now routine practice. A relevant instrumental advance was achieved when atomic force microscopy (AFM) was applied to study the features of crystal faces, giving new impulse to a topic that had always been the center of thorough research [3.15–18].

This chapter is devoted to the morphology of crystals grown from solution. In the first part, the theoretical equilibrium and growth shapes of crystals are treated from the thermodynamic and atomistic points of view. In the second part the factors affecting crystal habit will be considered with some specific examples. High-temperature solution growth, mass, and protein crystallization are excluded to limit the scope of the chapter.

3.1 Equilibrium Shape

When equilibrium is reached between a crystalline phase and its surroundings, the statistical amount of growth units exchanged between the two phases is the same and does not change with time. This implies that the crystallized volume remains constant, but nothing is specified about many important questions, such as:

1. The surface of the crystals, i. e., how large its extension is and which $\{hkl\}$ forms enter the equilibrium shape (ES).
2. The difference, if any, between the stable ES of a crystal immersed in either a finite or infinite mother phase and the unstable shape obtained when the activation energy for nucleation is reached.
3. How does the ES change when some adhesion is set up between the crystal and a solid substrate?
4. How can solvent and impurity concentrations affect the ES?

To address these questions, a few elementary concepts must be fixed to structure our language and a simple but effective crystal model adopted in the following.

3.1.1 The Atomistic Approach: The Kossel Crystal and the Kink Site

Let us consider a perfect monoatomic, isotropic, and infinite crystal. The work needed to separate an atom occupying a *mean lattice site* from all its n neighbors is $\varphi^{\text{sep}} = \sum_i^n \psi_i$, where ψ_i is the energy binding one atom to its i th neighbor. We will see later on that this peculiar site really exists and is termed a *kink*. The potential energy (per atom) of the crystal will be $\varepsilon_p^{\text{co}} = -(1/2)\varphi^{\text{sep}}$. The simplest model, valid for homopolar crystals, is due to *Kossel* [3.19]. Atoms are replaced by elementary cubes bounded by pair interactions, $\psi_1, \psi_2, \dots, \psi_n$: the separation work between the first, second, and n th neighbors, with the pair potential decreasing with distance, $\psi_1 > \psi_2 > \dots > \psi_n$ (Fig. 3.1a). In the first-neighbors approximation, the separation work for an atom lying in the crystal bulk is $\varphi^{\text{sep}} = 6\psi_1$. Thus, $\varepsilon_p^{\text{co}} = -3\psi_1$. On the other hand, $\varepsilon_p^{\text{co}}$ represents the variation of the potential energy that an atom undergoes when going from the vapor to a *mean lattice site*, which coincides with a well-defined surface site, as suggested by *Kossel* [3.19] and *Stran-ski* [3.2]. Once an atom has entered this special site, the potential energy variation of the considered system is equal to $-3\psi_1$ and so the separation work for

Fig. 3.1 (a) Kossel crystal; separation work between first (ψ_1), second (ψ_2), and third (ψ_3) neighbors. (b) When an atom enters a kink, there is a transition in the potential energy, the difference between final and initial stage being $-3\psi_1$ (first neighbors)

an atom occupying this site is $\varphi_{\text{co}} = 3\psi_1$ (Fig. 3.1b). A *kink* is the name adopted worldwide for this site, for practical reasons. Different historical names have been given: *repetitive step* [3.2, Z. Phys. Chem.] and *half-crystal position* [3.2, Annu. Univ. Sofia], both related to the physics of the site. In fact, deposition or evaporation of a growth unit onto/from a kink reproduces another kink, thus generating an equal probability for the two processes [3.20]. Moreover, the chemical potential (μ) of a unit in a kink is equal to that of the vapor. Hence, *kinks are crystal sites in a true (and not averaged) thermodynamic equilibrium*, as will be shown below.

3.1.2 Surface Sites and Character of the Faces

Flat (F) faces. A crystal surface, in equilibrium with its own vapor and far from absolute zero temperature, is populated by steps, adsorbed atoms, and holes. In the Kossel model all sites concerning the adsorption and the outermost lattice level are represented (Fig. 3.2). The percentage of corner and edge sites is negligible for an infinite crystal face, and hence we will confine our attention to the *adsorption and incorporation sites*. Crystal units can adsorb either on the surface terraces (ad_s) or on the steps (ad_l), with the same situation occurring for the incorporation sites (in_s, in_l).

Fig. 3.2 The different types of faces of a Kossel crystal: {100}-F, {111}-K, and {110}-S faces. Adsorption (ad_s , ad_l) and incorporation (in_s , in_l) sites are shown on surfaces and steps. The uniqueness of the K (kink) site is also shown

The binding energies of *ad*-sites and *in*-sites are complementary to one another

$$\begin{aligned}\varphi_{ad_s} + \varphi_{in_s} &= \varphi_{ad_l} + \varphi_{in_l} \\ &= 2\varphi_{kink} \rightarrow \varphi_{ad} + \varphi_{in} = 2\varphi_{kink},\end{aligned}\quad (3.1)$$

which is generally valid since it depends neither on the type of face, nor on the crystal model, nor on the kind of lattice forces [3.21, p. 56]. The interaction of the unit in the kink with the crystal (φ_{kink}) consists of two parts. The first represents its *attachment energy* (φ_{att}) with all the *crystal substrate*, and coincides with that of an ad-unit, which implies

$$\varphi_{att} = \varphi_{ad}. \quad (3.2a)$$

The second is its *slice energy* (φ_{slice}), i.e., the interaction with the half of the outermost crystal slice, $\varphi_{slice} = (\omega/2)$, where ω is the interaction of the unit with all of its slice. Thus

$$\varphi_{in} = \varphi_{att} + \omega, \quad (3.2b)$$

and, from relation (3.1)

$$\varphi_{kink} = \varphi_{att} + \varphi_{slice}. \quad (3.2c)$$

Relation (3.2c) states that φ_{att} and φ_{slice} of a growth unit are complementary to one another. In fact, since

φ_{kink} is constant for a given crystal, the higher the lateral interaction of one unit, the lower its interaction with the subjacent crystal. This criterion is of the utmost importance for understanding the growth morphology of crystals. Moreover, the binding of a growth unit must fulfil the qualitative inequality: $\varphi_{ad} < \varphi_{kink} < \varphi_{in}$. The quantitative treatment was elegantly addressed by Kaischew [3.3, 4], who calculated the coverage degree (θ_i) and other related quantities for every *i*-site of the surface drawn in Fig. 3.2

$$\theta_i = \{1 + \exp[(\varphi_{kink} - \varphi_i)/(k_B T)]\}^{-1}, \quad (3.3)$$

where k_B is the Boltzmann constant. For a (001) Kossel surface and within the first-neighbors approximation, having assumed for the binding energy the standard value $\psi_1 = 4k_B T$ (valid for Au crystals not far from the melting point), the set of results shown in Table 3.1 was obtained.

From Table 3.1 it follows that:

1. Kinks are the only sites in thermodynamic equilibrium, being half filled and half empty at the same time.
2. Ad-units form a very dilute layer (row) which moves randomly on the surface (step edge) and hence cannot belong to the crystal.
3. In-units belong to the crystal, from which they may escape, generating a temporary hole, with a very low exchange frequency with respect to the other sites.

Looking at the face as a whole, the face profile can neither advance nor move backwards: hence, the face is in *macroscopic equilibrium*. Fluctuations around the equilibrium cannot change its flatness since the lifetime of the growth units in the ad-sites is very short and the vacancies generated among the in-sites are filled again in

Table 3.1 Coverage degree (3.3) and exchange frequency of growth units in the main surface sites of the (001) face of a Kossel crystal, assuming $\psi_1 = 4k_B T$ (after [3.21]). The exchange frequency is the reciprocal of the mean time between two successive evaporation (or condensation) events on the same *i*-site (i.e. s^{-1} indicates the number of exchanges per unit time in a given site)

Type of surface site	Separation work	Coverage degree θ_i	Exchange frequency (s^{-1})
$ad_{surface}$	ψ_1	0.0003	3.06×10^7
ad_{ledge}	$2\psi_1$	0.0180	3.02×10^7
kink	$3\psi_1$	1/2	1.54×10^7
in_{ledge}	$4\psi_1$	0.9820	5.55×10^6
$in_{surface}$	$5\psi_1$	0.9997	1.03×10^4

even shorter time. So, this kind of *equilibrium face* has been named an F-type (flat) face.

Kinked (K) and Stepped (S) Faces. The uniqueness of F-faces is even more evident when considering the behavior of the {111} form of a Kossel crystal, near the equilibrium. Only kinks can be found on this surface and hence only one type of binding exists ($3\psi_1$) among growth units, within the first neighbors. Since in this case no units exhibit bonds in their slice, $\omega = 0$, which implies: $\varphi_{ad} = \varphi_{kink} = \varphi_{in}$. With every ad-unit transforming into an in-unit, the surface profile is not constrained and hence fluctuates, with the mother phase, around the equilibrium. This interface is diffuse and the corresponding faces are termed K (kinked) faces.

The behavior of the {110} form may be thought of as midway between that of F- and K-faces, since only ledge-type sites exist, apart from the kinks. Any fluctuation near the equilibrium can lead either to the evaporation of an entire [100] step or to the growth of a new one. In the first case, it is sufficient that a unit leaves an in-ledge site to promote step evaporation, while in the second case the formation of an ad-ledge site automatically generates two kinks, allowing the filling of a new step. Both processes are not correlated, even for contiguous steps, since there are no lateral bonds ($\omega = 0$) in the outermost (110) slice; thus, steps can form (or disappear) independently of each other and may bunch, giving rise to an undulating profile around the zone axis. Parallel steps being the feature of this kind of surface, the corresponding faces are termed S-type (stepped) faces.

3.1.3 The Equilibrium Crystal – Mother Phase: The Atomistic Point of View

Here we will deal with the equilibrium between a crystal and its vapor; however, *our conclusions can be basically applied to solutions and melts as well*. Let us consider a Kossel crystal built by n^3 units (each having mass m and vibration frequency ν). Since the work to separate two first neighbors is ψ , the mean evaporation energy of the n -sized crystal is easily calculated

$$\langle \Delta H \rangle_{cn} = 3\psi[1 - (1/n)] = \varphi_{cn} . \quad (3.4a)$$

Then, for an infinite-sized crystal,

$$\langle \Delta H \rangle_{c\infty} = 3\psi = \varphi_{c\infty} = \text{const} . \quad (3.4b)$$

This means that the *units belonging to the crystal surface* reduce the value of the mean evaporation energy

and so they *cannot be neglected when dealing with finite crystals*.

An Infinite Crystal and Its Mother Phase

As shown in Appendix 3.A, the equilibrium pressure (p_{eq}^∞) between a monoatomic vapor and its infinite crystalline phase decreases with its evaporation work $\varphi_{c\infty} = (\varepsilon_v - \varepsilon_{c\infty})$, according to

$$p_\infty^{eq} = [(2\pi m)^{3/2} (k_B T)^{-1/2} \nu^3] \exp(-\varphi_{c\infty}/(k_B T)) , \quad (3.5a)$$

ε_v and $\varepsilon_{c\infty}$ being the potential energy of a unit in the vapor and in the infinite crystal, respectively. The term $p dV$ can be neglected in $\langle \Delta H \rangle_{c\infty}$ with respect to the term (dU). Assuming, as a reference level, $\varepsilon_v = 0$, it is easy to show that $\langle \Delta H \rangle_{c\infty} = \varphi_{c\infty} = -\varepsilon_{c\infty}$.

The Finite Crystal – The Link to the Thermodynamic Supersaturation

When dealing with finite crystals (3.5a) transforms simply by changing $\varepsilon_{c\infty}$ with ε_{cn} , which is the potential energy of a unit in the finite crystal. It ensues that $\varphi_{cn} = (\varepsilon_v - \varepsilon_{cn})$. The frequency (ν) does not vary from large to small crystal size, so

$$p_n^{eq} = (2\pi m)^{3/2} (k_B T)^{-1/2} \nu^3 \exp(-\varphi_{cn}/(k_B T)) . \quad (3.5b)$$

From (3.5a) and (3.5b) the following fundamental relation is obtained:

$$p_n^{eq} = p_\infty^{eq} \exp[(\varphi_{c\infty} - \varphi_{cn})/(k_B T)] . \quad (3.5c)$$

Since $\varphi_\infty > \varphi_n$, (3.5c) shows that *the equilibrium pressure for finite crystals is higher than that for infinite ones*. This can also be written

$$\varphi_{c\infty} - \varphi_{cn} = k_B T \ln (p_n^{eq}/p_\infty^{eq}) = k_B T \ln \beta , \quad (3.6)$$

where $\beta = p_n^{eq}/p_\infty^{eq} = (p_\infty^{eq} + \Delta p)/p_\infty^{eq} = 1 + \sigma$ is the *supersaturation ratio* of the vapor with respect to the finite crystal. The (percentage) distance from equilibrium is $\sigma = (\Delta p/p_\infty^{eq})$, the exceeding pressure being $\Delta p = p_n^{eq} - p_\infty^{eq}$.

Equilibrium can also be viewed in terms of chemical potentials. Using the Helmholtz free energy, the chemical potentials, per unit, of the infinite and finite crystal read: $\mu_{c\infty} = -\varphi_{c\infty} - Ts_{c\infty}$ and $\mu_{cn} = -\varphi_{cn} - Ts_{cn}$. The vibrational entropies per unit, $s_{c\infty}$ and s_{cn} , are very close. Thus $\varphi_{c\infty} - \varphi_{cn} = \mu_{cn} - \mu_{c\infty} = \Delta\mu$ (Fig. 3.3). Hence, the following master equation for the equilibrium is obtained:

$$\Delta\mu = k_B T \ln \beta , \quad (3.7)$$

Fig. 3.3 Potential energy ε , evaporation work φ , and chemical potential μ of a growth unit in the vacuum, in a *mean site* of both finite and infinite crystal. $\Delta\mu = \mu_{cn} - \mu_{c\infty}$ is the thermodynamic supersaturation

where $\Delta\mu$ is the *thermodynamic supersaturation*. In heterogeneous systems a unit spontaneously goes from the higher chemical potential (μ') to the lower one (μ''). During the transition a chemical work ($\mu'' - \mu'$) = $-\Delta\mu$ is gained, per growth unit.

The equilibrium between a finite crystal and its surroundings is analogous to the equilibrium of a spherical liquid drop of radius r (finite condensed phase 2) immersed in its own vapor (infinite dispersed phase 1). The phenomenological treatment is detailed in [3.21], where the two different equilibria are compared in the same way as we dealt with the atomistic treatment. Hence, one obtains the Thomson–Gibbs formula for droplets

$$\Delta\mu = k_B T \ln(p/p_{eq}) = \Omega_2 p_\gamma = 2\Omega_2(\gamma/r), \quad (3.8)$$

where:

1. p_{eq} is the pressure of the vapor in equilibrium with a flat liquid surface
2. γ and Ω_2 are the surface tension at the drop–vapor interface and the molecular volume of the drop, respectively
3. The capillarity pressure p_γ at the drop interface defined by Laplace's relation ($p_\gamma = 2\gamma/r$) equilibrates the difference between the internal pressure of the drop (p_r) and the actual vapor pressure (p): $p_\gamma = (p_r - p)$.

The ratio (p/p_{eq}) is nothing else than β . When working with ideal or nonideal solutions, β is expressed by the concentrations (c/c_{eq}) or by the activities (a/a_{eq}), respectively. When a crystal is considered instead of a liquid drop, the system is no longer isotropic and then

the radius r represents only the *size* of the crystal, as we will see later on. Nevertheless, the Thomson–Gibbs formula continues to be valid and expresses the relation among the deviation $\Delta\mu$ of the solution from saturation, the tension γ_{cs} of the crystal–solution interface, and the size of the crystals in equilibrium with the solution.

3.1.4 The Equilibrium Shape of a Crystal on a Solid Substrate

This topics has been deeply treated by Kern [3.22], who considered simultaneously both mechanical (capillary) and chemical (thermodynamic) equilibrium to obtain the ES of a crystal nucleating on a substrate from a dispersed phase. In preceding treatments, the Curie–Wulff condition and the Wulff theorem [3.23] only took into account the minimum of the crystal surface energy, the crystal volume remaining constant. According to [3.22], when n_A units of a phase A (each having volume Ω) condense under a driving force $\Delta\mu$ on a solid substrate B (heterogeneous nucleation) to form a three-dimensional (3-D) crystal (Fig. 3.4), the corresponding variation of the free Gibbs energy reads

$$\Delta G_{\text{hetero}}^{3-D} = -n_A \times \Delta\mu + (\gamma_i^A - \beta_{\text{adh}})S_{AB} + \sum_j \gamma_j^A S_j^A, \quad (3.9)$$

where the second and the third term represent the work needed to generate the new crystal–substrate interface of area S_{AB} and the free crystal surfaces (of surface tension γ_j^A and area S_j^A), respectively.

The term $(\gamma_i^A - \beta_{\text{adh}})S_{AB}$ comes from the balance between the surface work lost ($-\gamma_B \times S_{AB}$) and gained ($\gamma_{AB} \times S_{AB}$) during nucleation. It is obtained from Dupré's formula: $\gamma_{AB} = \gamma_B + \gamma_i^A - \beta_{\text{adh}}$, where γ_{AB} is the crystal/substrate tension, γ_B is the surface tension of the substrate, γ_i^A is the surface tension of

Fig. 3.4 Surface parameters involved in the balance of the free Gibbs energy variation when n_A units of a phase A condense on a solid substrate B to form a 3-D crystal (heterogeneous nucleation)

the i -face of the A crystal (when considered not in contact with the substrate), and β_{adh} stands for the specific crystal/substrate adhesion energy. At the (unstable) equilibrium of the nucleation any variation of $\Delta G_{\text{hetero}}^{3-D}$ must vanish. Then, under the reasonable assumption that also the specific surface tensions do not vary for infinitesimal changes of the crystal size,

$$d(\Delta G_{\text{hetero}}^{3-D}) = -dn_A \times \Delta\mu + (\gamma_i^A - \beta_{\text{adh}}) dS_{AB} + \sum_j \gamma_j^A dS_j^A = 0. \quad (3.10)$$

The fluctuation dn_A is related to those of the face areas (dS_j^A and dS_{AB}) and to their distances (h_j and h_s) with respect to the crystal center. Then, (3.10) may be written in terms of dS_j^A and dS_{AB} . Its solution is a continuous proportion between the energies of the faces and their h_j and h_s values

$$\begin{aligned} \frac{\gamma_1^A}{h_1} = \frac{\gamma_2^A}{h_2} = \dots = \frac{\gamma_j^A}{h_j} = \frac{\gamma_i^A - \beta_{\text{adh}}}{h_s} \\ = \text{const} = \frac{\Delta\mu}{2\Omega}. \end{aligned} \quad (3.11)$$

This is the *unified Thomson–Gibbs–Wulff (TGW) equation*, which provides the ES of a crystal nucleated on a solid substrate:

1. The ES is a polyhedron limited by faces whose distances from the center are as shorter as lower their γ values.
2. The distance of the face in contact with the substrate will depend not only on the γ value of the lattice plane parallel to it, but also on its adhesion energy.
3. The faces entering the ES will be only those limiting the *most inner* polyhedron, its size being determined once $\Delta\mu$ and one out of the γ values are known.

The analogy between the crystal ES and that of a liquid drop on solid substrates is striking. It is useful to recall Young's relation for the mechanical equilibrium of a liquid drop on a substrate (Fig. 3.5)

$$\gamma_{\text{sl}} = \gamma_{\text{lv}} \cos \alpha + \gamma_{\text{sv}}, \quad (3.12a)$$

where α is the contact angle and γ_{sl} , γ_{lv} , and γ_{sv} are the surface energies of the substrate–liquid, liquid–vapor, and substrate–vapor interfaces, respectively. Besides, from Dupré's relation one obtains

$$\gamma_{\text{sl}} = \gamma_{\text{sv}} + \gamma_{\text{lv}} - \beta_{\text{adh}}. \quad (3.12b)$$

Since $-1 \leq \cos \alpha \leq 1$, the range of the adhesion energy (wetting) must fulfil the condition

$$2\gamma_{\text{lv}} \geq \beta_{\text{adh}} \geq 0. \quad (3.12c)$$

Adhesion values affect the sign of the numerator in the term $(\gamma_i^A - \beta_{\text{adh}})/h_s$ (3.11).

The ES of the crystal is a nontruncated polyhedron when the crystal/substrate adhesion is null, as occurs for homogeneous nucleation. However, as the adhesion increases, the truncation increases as well, reaching its maximum when $\beta_{\text{adh}} = \gamma_i^A$. If the wetting

Fig. 3.5 Analogy between the equilibrium shape of a liquid drop on a solid substrate and that of a crystal, both heterogeneously nucleated. The adhesion energy β_{adh} rules both the contact angle of the drop with the substrate and the *crystal truncation*

further increases the truncation decreases, along with the thickness of the crystal cup. When β_{adh} reaches its extreme value, $2\gamma_i^A$, the crystal thickness reduces to a *monomolecular* layer.

The Equilibrium Shape of a Finite Crystal in Its Finite Mother Phase

Microscopic crystals can form in fluid inclusions captured in a solid, as occurs in minerals [3.25], especially from solution growth under not low supersaturation and flow. If the system fluctuates around its equilibrium temperature, the crystal faces can exchange matter among them and with their surroundings: then crystals will reach their *ES*, after a given time. *Bienfait* and *Kern* [3.24], starting from an inspired guess by *Klija* and *Lemlein* [3.26], first observed the *ES* of NH_4Cl , NaCl , and KI crystals grown in small spherical inclusions (10–100 μm) filled by aqueous solution (Fig. 3.6). The crystals contained in each inclusion (initially dendrites) evolve towards a single convex polyhedron and the time to attain the *ES* is reasonable only for microscopic crystals and for droplet diameter of a few millimeters. The *ES* so obtained did not correspond to

the maximum of the free energy (unstable equilibrium) but to its minimum, and then to a stable equilibrium. Finally, it was shown that both unstable and stable *ESs* are homothetic but with different sizes.

3.1.5 The Stranski–Kaischew Criterion to Calculate the Equilibrium Shape

Without Foreign Adsorption

In the preceding sections, the surface tensions of the $\{hkl\}$ forms have been considered to be independent of crystal size. This is true when the crystal exceeds microscopic dimensions, but is no longer valid for those sizes which are very interesting both in the early stages of nucleation and in the wide field of nanosciences. In these cases, it should be reasonable to drop the use of the surface tension values, which are macroscopic quantities, to predict the equilibrium shape of micro- and nano-crystals. To face this problem, it is useful to recall the brilliant path proposed by *Stranski* and *Kaischew* [3.21, p. 170]. Their method, named the *criterion of the mean separation works*, is based on the idea that the mean chemical potential $\langle\mu\rangle_{c,m} = (1/m) \sum_{j=1}^m \mu_{j,c}$ averaged over all m units building the outermost layer of a finite facet, must be constant over all the facets, once the phase equilibrium is achieved. The chemical potential of a unit in a kink (Appendix 3.A) is

$$\mu_{c\infty} = -\varphi_{\text{kink}} - k_B T \ln \Omega_c + \mu^0, \quad (3.13a)$$

and, by analogy, in a j -site of the surface

$$\mu_{j,c} = -\varphi_{j,c} - k_B T \ln \Omega_j + \mu^0. \quad (3.13b)$$

The mean vibrational volumes being the same for every crystal sites, one can write for a generic site and especially at low temperature

$$\mu_{j,c} \approx -\varphi_{j,c} + \text{const}. \quad (3.14)$$

At equilibrium between a small crystal and its vapor: $\mu^{\text{gas}} = \langle\mu\rangle_{c,m}$. Subtracting the equality which represents the equilibrium between an infinite crystal and its saturated vapor ($\mu_{\text{saturated}}^{\text{gas}} = \mu_{c\infty}$) and applying relation (3.14), one can finally obtain

$$\begin{aligned} \Delta\mu &= \mu^{\text{gas}} - \mu_{\text{saturated}}^{\text{gas}} = \langle\mu\rangle_{c,m} - \mu_{c\infty} \\ &\approx \varphi_{\text{kink}} - \langle\varphi\rangle_{c,m}. \end{aligned}$$

That represents the *Thomson–Gibbs formula*, valid for every face of small-sized crystals

$$\varphi_{\text{kink}} - \langle\varphi\rangle_{c,m} \approx \Delta\mu = k_B T \ln \beta, \quad (3.15)$$

Fig. 3.6 The evolution towards equilibrium of NH_4Cl dendrites formed in an aqueous solution droplet (closed system) (after [3.24]). The total surface energy is minimized in passing from the dendritic mass to a single convex polyhedron at constant volume and T (equilibrium shape). Droplet size: 100 μm

which allows one to determine the β value at which a unit (lying on a given face) can belong to the ES. Using (3.15), the ES can be determined without using the γ values of the different faces.

Let n_{01} and n_{11} be the number (not known a priori) of units in the most external $\langle 01 \rangle$ and $\langle 11 \rangle$ rows of a 2-D Kossel crystal (Fig. 3.7). Within the second neighbors, the mean separation works for these rows are

$$\begin{aligned} \langle \varphi \rangle_{01} &= (1/n_{01})[2\psi_1(n_{01} - 1) + \psi_1 + 2\psi_2 n_{01}] \\ &= 2\psi_1 + 2\psi_2 - (\psi_1/n_{01}), \end{aligned} \quad (3.16a)$$

$$\begin{aligned} \langle \varphi \rangle_{11} &= (1/n_{11})[2\psi_2(n_{11} - 1) + \psi_2 + 2\psi_1 n_{11}] \\ &= 2\psi_1 + 2\psi_2 - (\psi_2/n_{11}). \end{aligned} \quad (3.16b)$$

The separation work from the kink is $\varphi_{\text{kink}} = 2\psi_1 + 2\psi_2$ and hence from (3.15) it ensues that

$$\begin{aligned} \Delta\mu &= \varphi_{\text{kink}} - \langle \varphi \rangle_{01} = \varphi_{\text{kink}} - \langle \varphi \rangle_{11} \\ &= (\psi_1/n_{01}) = (\psi_2/n_{11}), \end{aligned} \quad (3.16c)$$

which represents both the phase equilibrium and the ES of the 2-D crystal. In fact the ratio between the lengths of the most external rows is obtained as

$$(n_{01}/n_{11}) = (\psi_1/\psi_2). \quad (3.17)$$

Equation (3.17) is nothing other than Wulff's condition $(h_{01}/h_{11}) = (\gamma_{01}/\gamma_{11})$ applied to this small crystal (3.11) [3.21, p. 172].

The criterion of the mean separation work can also answer a question fundamental to both equilibrium and growth morphology: how can we predict whether a unit is stable or not in a given lattice site? Let us consider, as an example, the unit lying at corner X of the 2-D Kossel crystal (Fig. 3.7). Its separation work, within the second neighbors, reads $\varphi_X = 2\psi_1 + \psi_2$. Stability will occur only if the separation work of the unit X is higher than the mean separation work of its own row, i.e., $\varphi_X \geq \langle \varphi \rangle_{01}$ and hence, from (3.16c), $\varphi_X \geq \varphi_{\text{kink}} - \Delta\mu$. It ensues that $2\psi_1 + \psi_2 \geq 2\psi_1 + 2\psi_2 - \Delta\mu$. Finally, one obtains $\Delta\mu = k_B T \ln \beta \geq \psi_2$, which transforms to

$$\beta \geq \beta^* = \exp(\psi_2/k_B T). \quad (3.18)$$

This means that, when β is lower than the critical β^* value, the unit must escape from the site X, thus generating an ES which is no longer a square, owing to the beginning of the $\langle 11 \rangle$ row. In other words, the absolute size (n_{01}, n_{11}) of the crystal homothetically decreases with increasing β (ψ_1 and ψ_2 being constant), as ensues from (3.16c). Since $\psi_1 > \psi_2$, $n_{01} > n_{11}$ and the ES will assume an octagonal shape dominated by the four equivalent $\langle 01 \rangle$ sides, the octagon reducing to the square

Fig. 3.7 To derive the equilibrium shape of a 2-D Kossel crystal by the criterion of the mean separation work, only the 1st, 2nd, ..., n -th-neighbors interactions are needed. The figure illustrates the scheme for the second-nearest neighbors approximation, the kink energy (φ_{kink}), the stability criterion for a unit X occupying a corner site and, finally, the 2-D equilibrium shape and size for $(\psi_1/\psi_2) = 1.5$ and for increasing supersaturation ($\Delta\mu$) values

when the number of units along the $\langle 11 \rangle$ sides is reduced to $n_{11} = 1$. As $\Delta\mu = (\psi_2/n_{11})$, this occurs when $\Delta\mu = \psi_2$, which exactly reproduces what we have just found in (3.18).

With Foreign Adsorption

In growth from solution a second component (the solvent) intervenes in the interfacial processes, since its molecules interact strongly with the crystallizing solute. Here we are interested in studying how the ES of a crystal is affected by the presence of a foreign component. Two approaches exist in order to give a full answer to this problem:

1. The *thermodynamic* approach, which allows one to forecast the variation $d\gamma$ of the surface tension γ of a face due to the variation $d\mu_i$ of the chemical potential of component i of the system, when it is adsorbed. To calculate $d\gamma$ for a flat face one has to apply Gibbs' theorem [3.22, p. 171]

$$d\gamma = -s^{(s)} dT - \sum_i \Gamma_i d\mu_i, \quad (3.19)$$

where $s^{(s)}$ is the specific surface entropy and $\Gamma_i = -(\partial\gamma/\partial\mu_i)_{T,s,\mu_{j \neq i}}$ corresponds to the excess of the surface concentration of component i . Solving (3.19) is not simple, even at constant T , since one has to know the functional dependence of Γ_i on

μ_i and hence on the activity a_i of component i . This means that one has to know Γ_i , which ultimately represents the adsorption isotherm of component i on a given face.

2. The approach grounded on the *atomistic view of equilibrium* proposed by Stranski [3.27, 28]. This model is based on the simplifying assumptions that foreign ad-units have the same size as those building the adsorbing surface (Kossel model) and that only first-neighbor interactions are formed between ad-units and the substrate. Three types of adsorption site are defined (Fig. 3.8), each of them having its own binding energy.

From (3.19) it ensues that adsorption generally lowers the surface tension of the substrate ($\Delta\gamma < 0$), so γ increases when an adsorption layer is reversibly desorbed. Let us denote the desorption work by $w = -\Delta\gamma \times a$, representing the increase per ad-site of the surface tension of the substrate (where a is the mean area occupied by an ad-unit) [3.29–31]. Thermodynamics allows to evaluate w , according to the type of adsorption isotherm [3.21, p. 175]

$$w = -k_B T \ln(1 - \theta) - (\omega/2)\theta^2 \quad \text{(Frumkin–Fowler type)}, \quad (3.20a)$$

$$w = -k_B T \ln(1 - \theta) \quad \text{(Langmuir type)}, \quad (3.20b)$$

valid when ω , the lateral interaction of the ad-unit with the surrounding, vanishes and

$$w = -k_B T \times \theta \quad \text{(Henry type)}, \quad (3.20c)$$

when the coverage degree in ad-units is low ($\theta \ll 1$). In the last case one can compare the θ values of the different sites remembering that, at given bulk concentration of foreign units, the coverage degree for an isolated ad-unit behaves as $\theta \propto \exp(\varphi_{\text{ads}}/(k_B T))$. Here, φ_{ads} is the

binding energy of the ad-unit with the substrate. From (3.20c) one can write

$$\frac{w_i}{w_j} = \frac{\theta_i}{\theta_j} = \exp \frac{(\varphi_{\text{ads}}^i - \varphi_{\text{ads}}^j)}{k_B T}, \quad (3.21)$$

which shows that the difference in the desorption works is very sensitive to the φ_{ads} value. This can be verified by applying (3.21) to the three sites in Fig. 3.8a of a cubic Kossel crystal and remembering that, in this case, φ_{ads} is equal to ψ_{ads} , $2\psi_{\text{ads}}$, and $3\psi_{\text{ads}}$, where $\psi_{\text{ads}} = k_B T$, $2 \times k_B T$, $3 \times k_B T, \dots$ is the energy of one adsorption bond. An important consequence of this reasoning is that *the chemical potential of an infinite crystal (and hence its solubility) is not changed by the adsorption of impurities on its surfaces*, as is proved by the balance detailed in Fig. 3.8b, which represents the initial and final stages of the desorption of a foreign unit from a kink site.

Let us now evaluate how the ES of a finite crystal changes, by applying the criterion of the mean separation works to the mentioned Stranski adsorption model. The stability of a unit in the corner site X when adsorption occurs (Fig. 3.9a) can be compared with that obtained without adsorption (3.18). The separation work of a unit in X is $\varphi_X^{\text{ads}} = 2\psi_1 + \psi_2 + 2w_1 - w_2$, where w_1 and w_2 are the desorption works for the two ad-sites, respectively.

The stability criterion requires $\varphi_X^{\text{ads}} \geq \langle \varphi \rangle_{01}$ and hence, from (3.16c), $\varphi_X^{\text{ads}} \geq \varphi_{\text{kink}} - \Delta\mu$.

Since $\varphi_{\text{kink}} = 2\psi_1 + 2\psi_2$, stability occurs only when $\Delta\mu \geq \psi_2 - (2w_1 - w_2)$. This implies

$$\beta_{\text{ads}}^* \geq \exp\{[\psi_2 - (2w_1 - w_2)]/(k_B T)\}. \quad (3.22)$$

Comparing (3.22) with (3.18) it turns out that the stability of the corner unit occurs at lower β value ($\beta_{\text{ads}}^* < \beta^*$) if $w_2 < 2w_1$. This means that, if the impurity fulfils the inequality $w_2 < 2w_1$, the ES is a pure square crystal at a β value lower than that predicted in pure growth medium. The $\langle 11 \rangle$ edges begin to appear when the corner units can escape from the crystal (instability of the X -site), i. e., if $\beta < \beta_{\text{ads}}^*$. On the contrary, if $w_2 > 2w_1$ the impurity adsorption does not favor the stability of the corner unit and an octagonal ES forms at a β value lower than that found in pure growth medium. Figure 3.9b illustrates how the smoothing of a 2-D K-face can be obtained with foreign adsorption [3.21, pp. 178–189]. The energy difference between the final and initial stages is that which we obtained for the X -site, so the conclusions are obviously those fulfilling (3.22). Figure 3.9c concerns the stability of an ad-unit (site A) on

Fig. 3.8 (a) The three types of adsorption sites on a Kossel crystal (only 1st neighbors interaction). Each ad-site has its binding energy: $w_1 < w_2 < w_3$. (b) Energy balance representing the initial a) and the final b) stage of the desorption of a foreign unit from a kink-site. The binding energy does not vary on the adsorbance (after [3.21])

the $\langle 10 \rangle$ edges in the presence of foreign adsorption. The separation work of a unit at A is $\varphi_A^{\text{ads}} = \psi_1 + 2\psi_2 + 2(w_2 - w_1)$. The stability criterion for this site requires

$$\beta_{\text{ads}}^* \geq \exp\{[\psi_1 - 2(w_2 - w_1)]/(k_B T)\}, \quad (3.23)$$

while, in analogy with (3.18), the stability criterion without impurities reads

$$\beta^* \geq \exp\left(\frac{\psi_1}{k_B T}\right). \quad (3.24)$$

Thus, the foreign adsorption favors the stability of the growth units at site A if $\beta_{\text{ads}}^* < \beta^*$ and hence if $w_2 > w_1$. If this occurs, $\langle 10 \rangle$ edges transform from flat to rough owing to the random accumulation of ad-units.

Transferring these results from 2-D to 3-D crystals, the conditions expressed by (3.22) and (3.23), respectively, rule the transition of character K \rightarrow F and F \rightarrow K due to foreign adsorption.

The changes in the ES when adsorption occurs can now be calculated, according to the Stranski–Kaischew principle of the *mean separation work*. This means that, when an entire $\langle 10 \rangle$ or $\langle 11 \rangle$ row is removed from a 2-D crystal in the presence of adsorbed impurities, the mean separation works must fulfil the condition $\langle \varphi \rangle_{01}^{\text{ads}} = \langle \varphi \rangle_{11}^{\text{ads}}$, in analogy with (3.16a) and (3.16b). From calculation it ensues that

$$\left(\frac{n_{01}}{n_{11}}\right)_{\text{ads}} = \frac{\psi_1 - 2(w_2 - w_1)}{\psi_2 - (2w_1 - w_2)}, \quad (3.25)$$

which can be compared with the analogous expression (3.17) obtained without foreign adsorption

$$\begin{aligned} \left(\frac{n_{01}}{n_{11}}\right)_{\text{ads}} : \left(\frac{n_{01}}{n_{11}}\right) &= \frac{\psi_1 - 2(w_2 - w_1)}{\psi_2 - (2w_1 - w_2)} : \frac{\psi_1}{\psi_2} \\ &= \frac{\psi_1 \psi_2 - \psi_2 \times 2(w_2 - w_1)}{\psi_1 \psi_2 - \psi_1 \times (2w_1 - w_2)}. \end{aligned} \quad (3.26)$$

Hence the importance of the $\langle 10 \rangle$ edges in the ES increases to the detriment of the $\langle 11 \rangle$ edges, if the condition $2(w_2 - w_1)/(2w_1 - w_2) < \psi_1/\psi_2$ is fulfilled. A simpler solution is obtained within the first-neighbors approximation ($\psi_2 = 0$, $\psi_1 = \psi$). Remembering that, without foreign adsorption, the ES is a pure square, in the presence of impurities some changes should occur. In this case, expression (3.25) reduces to $(n_{01}/n_{11})_{\text{ads}}^{\text{1st}} = (\psi - 2(w_2 - w_1))/(w_2 - 2w_1)$.

Fig. 3.9a–c The criterion of the mean separation works applied to the Stranski adsorption model in the second-neighbors approximation. (a) The first balance corresponds to the stability of the X site (*corner*) in the presence of foreign adsorption. (b) The second balance shows that the $\langle 11 \rangle$ row becomes smooth with foreign adsorption if $w_2 > 2w_1$. (c) The third balance describe the energies involved in calculating the stability of an ad-unit (site A) on the $\langle 10 \rangle$ edges in the presence of foreign adsorption. The figure has been inspired by [3.21]

The $\langle 11 \rangle$ row will exist if $n_{11} > 0$. Taking into account that necessarily $n_{10} > 0$, one must have simultaneously that $\psi > 2\psi(w_2 - w_1)$ and $w_2 > 2w_1$. The first inequality is verified by (3.23) since the ES of a finite crystal needs a supersaturated mother phase ($\beta_{\text{ads}}^* > 1$), so the only way for the $\langle 11 \rangle$ row to exist is for the second inequality also to be true, as found above. Summing up, the method of the *mean separation work* is a powerful tool to predict both qualitatively and quantitatively the ES of crystals, with and without foreign adsorption, without an a priori knowledge of the surface tension of their faces.

3.2 The Theoretical Growth Shape

When working with solution growth one usually has to deal with crystals having complex structures and/or low symmetry. In this case neither the Kossel model nor simple lattices, such as those related to the packing of rigid spheres, can be used to predict the most probable surface profiles. On the other hand, these profiles are needed both to evaluate the **ES** of crystals and for understanding the kinetics of a face. To do this, structural and energetic approaches have been developed.

3.2.1 The Structural Approach

The first works on theoretical growth morphology were grounded on structural considerations only and led to the formulation of the Bravais–Friedel–Donnay–Harker (BFDH) law [3.5, 6, 32]; see [3.33] for a recent review. According to this law, the larger the lattice distance d_{hkl} , the larger the morphological importance (**MI**) of the corresponding $\{hkl\}$ form

$$d_{h_1k_1l_1} > d_{h_2k_2l_2} \rightarrow \text{MI}(h_1k_1l_1) > \text{MI}(h_2k_2l_2), \quad (3.27)$$

$\text{MI}(hkl)$ being the relative size of a $\{hkl\}$ form with respect to the whole morphology. The inequality may also be viewed as the relative measure of the growth rate of a given form

$$R_{hkl} \propto (1/d_{hkl}) \quad (3.28)$$

once the *effective* d_{hkl} distances, due to the systematic extinction rules, are taken into account. Thus, the BFDH theoretical growth shape of a crystal can be obtained simply by drawing a closed convex polyhedron limited by $\{hkl\}$ faces whose distances from an arbitrary center are proportional to the reciprocal of the corresponding d_{hkl} values [3.5, 6]. The BFDH rule was improved [3.32], considering that many crystal structures show pseudosymmetries (pseudoperiods or subperiods), leading to extra splitting of the d_{hkl} distances, and hence to sublayers of thickness $(1/n) \times d_{hkl}$.

A typical example is that of the NaCl-like structures in which, according to the space group $Fm\bar{3}m$, the list of d_{hkl} values should be $d_{111} > d_{200} > d_{220}$, etc. Vapor-grown crystals show that the cube is the only growth form, while $\{111\}$ and $\{110\}$ forms can appear when crystals grow from aqueous solutions (both pure and in the presence of specific additives) [3.34]. This was explained [3.32] considering that the face-centered structural 3-D cell can also be thought of as a pseudo

unit cell (i.e., a neutral octopole) which, being primitive, leads to the cube as the theoretical growth shape.

The $R_{hkl} \propto (1/d_{hkl})$ structural rule works rather well since it implies an *energetic concept*. In fact, looking at the advancement of a crystal face as a layer-by-layer deposition, the energy released (per growth unit) when a d_{hkl} layer deposits on a fresh face is lower than that released by a sublayer since the interaction of the growth units slows down with their distance from the underlying face. Thus, the rule $R_{hkl} \propto (1/d_{hkl})$ is reasonable under the hypothesis that the face rate is proportional to the energy released when a growth unit attaches to it: $R_{hkl} \propto \text{probability of attachment}$. Nevertheless, this is a crude approximation, because neither the lateral interactions of the growth units nor the fact that only the flat faces can grow by lateral mechanism (i.e., layer by layer, as shown in Sect. 3.2.2) are considered.

3.2.2 Crystal Structure and Bond Energy: The Hartman–Perdok Theory

To go beyond these limitations, Hartman and Perdok (HP) looked at crystals as a 3-D arrays of bond chains building straight edges parallel to important $[uvw]$ lattice rows. Thus, *units* of the growth medium (**GU**) bind among themselves (through bonds in the first coordination sphere), forming more complex units that build, in turn, the crystal and reflect its chemical composition. These *building units* (**BU**) repeat according to the crystal periodicity, thus giving rise to *periodic bond chains* (**PBCs**). An example of a **PBC** is the set of equivalent **PBCs** running along the edges of the cleavage rhombohedron of calcite; these **PBCs** can be represented by the sequence shown in Fig. 3.10, where Ca^{2+} and CO_3^{2-} ions are the **GUs** assumed to exist in solution, the group CaCO_3 is the crystal **BU**, and the vector $\frac{1}{3}[\bar{4}41]$ is the period of the $[\bar{4}41]$ **PBC**. This **PBC** is stable, since the

Fig. 3.10 Schematic drawing of the **PBC** running along the $[\bar{4}41]$ edges of calcite crystal. (○) calcium, (Δ) carbonate ions. The **PBC** is stoichiometric; the repeat period is shown. The dipole moments, perpendicular to the chain axis, cancel each other

resultant dipole moment cancels out perpendicular to its development axis.

When applying the **HP** method to analyze a crystal structure, one must look, first of all, at the effective d_{hkl} spacing. Then, one has to search for the number of different **PBCs** that can be found within a slice of thickness d_{hkl} . Three kinds of faces can be distinguished, according to the number n of **PBCs** running within the d_{hkl} slice ($n \geq 2$, 1 or 0). Looking at the most interesting case ($n \geq 2$), the **PBCs** contained in this kind of slice have to cross each other, so allowing one to define:

1. An area A_{hkl} of the cell resulting from the intersection of the **PBCs** in the d_{hkl} slice
2. The *slice energy* (E_{sl}), which is half of the energy released when an infinite d_{hkl} slice is formed; its value is obtained by calculating the interaction energy (per **BU**) between the content of the A_{hkl} area and the half of the surrounding slice
3. The *attachment energy* (E_{att}), i.e., the interaction energy (per **BU**) between the content of the area A_{hkl} and the semi-infinite crystal underlying it.

The **BUs** within the area A_{hkl} are strongly laterally bonded, since they form (at least) two bonds with the end of the two semi-infinite chains (Fig. 3.11). This implies that a **BU** forming on this kind of faces is likely to be incorporated at the end of the chains, thus contributing to the advancement of the face in (at least) two directions, parallel to the face itself. Hence, the characteristic of these faces will maintain their flat profile, since they advance laterally until their outermost slice is filled. In analogy with what we obtained within the frame of the Kossel crystal model, these are F-faces. Moreover, their E_{sl} is a relevant quantity with respect to their E_{att} , due to the prevailing lateral interactions within the slice. From Fig. 3.11 it ensues that the energy

Fig. 3.11 Two **PBCs** within the slice d_{hkl} intersect in an elementary cell of area A_{hkl} , which occupies a kink site. The interaction of its content with half of the d_{hkl} slice gives the slice energy (E_{sl}); the interaction with all the crystal substrate gives its attachment energy (E_{att})

released (per **BU**) when the A_{hkl} content definitely belongs to the crystal is the crystallization energy (E_{cr}), which is a constant for a given crystal and hence for all crystal faces [3.35, p. 379]

$$E_{cr} = E_{att}^{hkl} + E_{sl}^{hkl} \quad (3.29)$$

This relation is of greatest importance to predict the growth shape of crystals, as can be understood when looking at the *kinetic meaning* of E_{att}^{hkl} . In fact, the central **HP** hypothesis is that, the higher the E_{att}^{hkl} value, the higher the probability that a **BU** will remain fixed to the (hkl) face, and thus of belonging to the crystal. It ensues that the E_{att}^{hkl} value becomes a relative measure of the normal growth rate of the $\{hkl\}$ form [3.36]

$$R_{hkl} \propto E_{att}^{hkl} \quad (3.30)$$

From (3.29) and (3.30) it follows that, as E_{sl} increases, both the attachment energy and the advancement rate of the face decrease. Examples par excellence can be found in layered crystal species such as the normal paraffins (C_nH_{2n+2}) and micas. Both cases are characterized by similar packing; in fact, in paraffin crystals, long-chain molecules are strongly laterally bonded within d_{00l} slices, while the interaction between successive slices is very weak; in micas, T-O-T sheets are built by strong covalent and ionic bonds whilst the interaction between them is ruled mainly by weak ionic forces. The best example is calcite, in which the E_{sl} of the $\{10\bar{1}4\}$ rhombohedron reaches 92% of the crystallization energy value and E_{att} reduces to account for the remaining 8%. This striking anisotropy explains, from one hand, the well-known cleavage properties of calcite and, on the other hand, the slowest growing of the $\{10\bar{1}4\}$ form, within a large β range and in the absence of impurities in the mother solution.

It is worth outlining the *similarity between the relation (3.2c) ruling the kink energy and the relation (3.29) defining the crystallization energy*

$$\varphi_{kink} = \varphi_{att} + \varphi_{slice} \rightarrow E_{cr} = E_{att}^{hkl} + E_{sl}^{hkl} \quad (3.31)$$

Both relationships can be expressed in energy/**BU**: the first relation concerns a single **GU** (atom, ion or molecule), while the second one is extended to a unit cell compatible with the d_{hkl} thickness allowed by the systematic extinction rules. This means that **HP theory permits one to predict the growth morphology of any complex crystal, through a brilliant extension of the kink properties to the unit cell of the outermost crystal layers.**

The example shown in Fig. 3.12a concerns the **PBC** analysis applied to the lithium carbonate structure

(space group $C2/c$). [001] PBCs are found along with another kind of PBC, running along the equivalent set of $\langle 110 \rangle$ directions. From this it ensues that the $\{110\}$ form has F-character, since two kinds of PBCs run within the allowed slice of d_{110} thickness. On the contrary, both $\{100\}$ and $\{010\}$ are S-forms, as no bond can be found between successive [001] PBCs within the slices of allowed thickness d_{200} and d_{020} , respectively. Figure 3.12b shows that only the $\{110\}$ prism exists in the [001] zone of a Li_2CO_3 crystal grown from pure aqueous solution, thus proving that the prediction obtained through the HP method is valid.

The choice of the BU is strategic for predicting both growth and equilibrium shapes. With reference to the preceding example, four different BUs can be found in Li_2CO_3 crystal, due to the distorted fourfold Li^+ coordination. Each of these BUs determines a different profile of the crystal faces and, consequently, different γ and E_{att} values. Hence, one has to search for all possible surface configurations and then calculate their corresponding γ and E_{att} values in order to choose those fulfilling the minimum-energy requirement.

Concerning methods to find PBCs and face characters, one has to carry out many procedures, ranging from the original visual method to computer methods, which began to be applied about 30 years ago and

reached their highest level of sophistication in elementary graph theory [3.11, 37–40], in which crystallizing GUs are considered as points and bonds between them as lines. A different computer method to find the surface profile with minimum energy was developed by Dowty [3.41], who searched for the plane parallel to a given (hkl) face cutting the minimum number of bonds per unit area, irrespective of the face character. This method has proved interesting as a preliminary step for calculating both equilibrium and growth crystal shapes. In the last 50 years, a lot of papers have been produced in which the theoretical growth morphology has been predicted for a wide variety of crystals exhibiting different types of bonds. The reader is invited to consult authoritative reviews on this subject [3.35, 42] and to proceed with caution in accepting predicted morphologies because there is a certain tendency to confuse, in practice, equilibrium and growth morphology.

3.2.3 The Effect of Foreign Adsorption on the Theoretical Growth Shape

In the original HP method, E_{att} is evaluated without considering either the temperature effect or the influence of the growth medium. Neglecting temperature does not imply a crude approximation on the predicted

Fig. 3.12a,b Comparison between the experimental morphology, in the [001] zone, of lithium carbonate crystal and the theoretical one (HP method). (a) [001] PBCs are seen up-down with bonds among them, within the d_{110} slices. The $\{110\}$ prism is an F-form; the $\{100\}$ and $\{010\}$ are S-forms (no bonds within the slices of d_{200} and d_{020} , respectively). (b) Scanning electron microscopy (SEM) image of Li_2CO_3 twinned crystal grown from aqueous solution, showing the dominance of the $\{110\}$ prism. The 100 twin plane is indicated

equilibrium and growth shape, when dealing with low-temperature solution growth. In fact both γ and E_{att} values are not particularly affected by the entropic term, in this case. On the contrary, a condensed phase around the crystal (the solvent) and/or specific added impurities can deeply modify the behavior of the crystal faces.

The Role of the Solvent

This topic has been carefully examined, first with the aim of predicting *qualitatively* how the crystal–solution interface is modified by the solvent, and then which the slow-growing faces are likely to be. To do this, the roughness of the interface has been quantified in terms of the so-called α -factor [3.43, 44] which defines the enthalpy changes taking place when a flat interface roughens. This factor, originally conceived for crystal–melt interface, has been modified for solution growth and is commonly expressed in two ways

$$\alpha = \xi_{hkl} \frac{\Delta H_s}{RT} \quad \text{or} \quad \alpha = \xi_{hkl} \left[\frac{\Delta H_f}{RT_m} - \ln X_s(T) \right], \quad (3.32a)$$

where ΔH_s represents the heat of solution at saturation, ΔH_f the heat of fusion, X_s the solubility, T_m the temperature of fusion, and ξ_{hkl} is a factor describing the anisotropy of the surface under consideration [3.44]. ξ_{hkl} is evaluated by means of HP analysis, since it is strictly related to the slice energy of the $\{hkl\}$ form

$$\xi_{hkl} = \frac{E_{hkl}^{\text{slice}}}{E_{\text{cr}}}. \quad (3.32b)$$

Three different situations occur, according to the α value:

1. When $\alpha \leq 3$, the interface is rough and the face behaves as a K- or S-face.
2. If $3 \leq \alpha \leq 5$, the interface is smoother (F-face) and the creation of steps on the surface becomes a limiting factor at low β -values (birth and spread of 2-D nuclei).
3. When $\alpha > 5$ the growth at low β is only possible with the aid of screw dislocations since the barrier for 2-D nucleation is too high.

Equations (3.32a) and (3.32b) clearly show that different $\{hkl\}$ forms should have different α -factor values, not only owing to the ξ_{hkl} anisotropy, but also because of the solubility and of the heat of solution. Thus, the crystal morphology will also be dependent on the growth solvent.

As mentioned above, the evaluation of the α -factor is useful for predicting if a crystal form can survive

against competition with other forms, but nothing can be deduced on the relative growth rates of the surviving forms. To overcome this drawback, solvent interaction with crystal surfaces was considered quantitatively by Berkovitch-Yellin [3.14, 45] who calculated the electrostatic maps of certain faces and identified the most likely faces for adsorption.

A clear example of the role played by the solvent is that concerning the theoretical equilibrium and growth forms of sucrose. We will not consider here its polar $\{hkl\}$ forms to avoid the complications due to the coupling of adsorption and polarity; rather we will confine our attention to the nonpolar $\{h0l\}$ forms. HP analysis shows that the theoretical growth morphology of sucrose agrees with the experimental one, obtained from pure aqueous solution, with the only exception of the $\{101\}$ form [3.46]. In fact, the $[010]$ PBCs are not connected by strong bonds (H-bonds in this case) within the d_{101} slice (Fig. 3.13a) and then $\{101\}$ should behave as an S-form. Nevertheless, the S-character does not agree with its high occurrence frequency ($\approx 35\%$), rather unusual for a stepped form. The way to get out of this discrepancy is composed of two paths.

First, *one has to carry out a quantitative HP analysis* considering the strength of the PBCs running within the d_{101} slice. The energies released when a molecule deposits on the top of different molecular chains (i.e., the end chain energy, ECE) have been calculated. It results that $\text{ECE}[010] = -0.525 \times 10^{-12}$ and $\text{ECE}[10\bar{1}] = -0.077 \times 10^{-12}$ erg/molecule. These interactions being attractive, two PBCs really exist in the d_{101} slice and $\{101\}$ is a F-form, contrarily to what was concluded through qualitative application of the HP method. However, its F-character is weak, due to the strong anisotropy between the two PBCs and its E_{att} value being too high with respect to those of the other $\{h0l\}$ forms, so that the $\{101\}$ form cannot belong to the growth shape of the crystal (Table 3.2 and Fig. 3.13b).

Secondly, one has to *consider the specificity of water adsorption* on the $\{101\}$ surfaces. In fact, even if H-bonds do not exist within a d_{101} slice at the crystal–solution interface, water adsorption can occur between two consecutive $[010]$ chains by means of two strongly adsorbed water molecules over a $[010]$ period. Then, a new $[11\bar{1}]$ PBC forms and the PBC $[10\bar{1}]$ results stronger on the outermost crystal layer than in the crystal bulk. Consequently, the F-character of the face is greatly enhanced. This kind of water adsorption is specific to this form, as all other faces in the $\{h0l\}$ zone are built by $[010]$ PBCs strongly bonded among them, without allowing free sites for bonding of interchain wa-

Fig. 3.13 (a) Projection along the [010] PBC of the sucrose structure. Each ellipse, containing two sucrose molecules, fixes the boundaries of a PBC. No bond can be found between two consecutive PBCs within a slice d_{101} , whilst bonds occur within the other $\{h0l\}$ forms. (b) Theoretical equilibrium and growth shapes of sucrose in the [010] zone, calculated without (full line) and with water adsorption (dotted line) (after [3.46])

ter molecules. New equilibrium and growth shapes are obtained (Fig. 3.13b), remembering that γ_{hkl} can be obtained from E_{att}^{hkl} through the relationship holding for molecular crystals [3.36], where the second-neighbors interactions are weak

$$E_{\text{att}}^{hkl} \cong \gamma_{hkl} \times 2A_{2D}^{hkl} / z, \quad (3.33)$$

where A_{2D}^{hkl} is the area of the unit cell related to the d_{hkl} slice and z are the molecules within it. Growth isotherms showed that the {101} form can grow by a spiral mechanism, thus proving its F-character, and that water desorption is the rate-determining process of its kinetics. Moreover, and for the first time, the idea of E_{att} was also successfully extended to the spiral steps running on the {101} surfaces, thus proving that the attachment energy at the spiral steps determines the growth shape of spirals, especially at low supersaturation values [3.47].

Table 3.2 Calculated surface (γ_{h0l} : erg cm⁻²) and attachment energies (E_{att}^{h0l} : 10⁻¹² erg/molecule) for the $\{h0l\}$ zone of sucrose crystal, in the crystal-vacuum system at $T = 0$ K

Form	{100}	{101}	{001}	{10 $\bar{1}$ }
γ_{h0l}	143	201	206	198
E_{att}^{h0l}	0.96	2.50	1.92	2.01

PBC analysis has been used, in recent times, as a preliminary step for predicting growth morphology in the presence of the solvent. A general and powerful kinetic model was elaborated by the *Bennema* school [3.13] in which growth mechanisms of the faces are considered, that is, spiral growth at low β -values and 2-D polynucleation at high β -values. Furthermore, to analyze the influence of the fluid phase on the crystal morphology, an interfacial analysis has been developed within the framework of inhomogeneous cell models [3.48, 49]. However, this model suffers from some limitations, since it is assumed that in solution growth the solute incorporation into the steps is governed by direct diffusion of molecules into the kinks. Experiments show that this is not always the case. Good examples are those of the growth isotherms obtained by the Boistelle group in Marseille for the normal paraffins. Surface diffusion is the rate-determining step for the {110} form of octacosane (C₂₈H₅₈) crystals [3.50], while coupled volume and surface diffusion effects dominate the growth rate of {001} form of hexatriacontane (C₃₆H₇₄) crystals growing from heptane solution [3.51, 52]. Another interesting case is that represented by the complementary {110} and {1 $\bar{1}$ 0} F-forms of sucrose crystals, which are ruled by volume and surface diffusion, respectively, when growing from pure aqueous solution between 30 and 40 °C [3.53, 54].

The modifications induced on E_{att} by the solvent have been evaluated theoretically by considering the relationship (3.33) holding for molecular crystals and obtaining a new expression for E_{att} , where the maximum number (n_s) of solvent molecules interacting with the surface unit cell (S_{hkl}) and their interaction energy (E_{hkl}^i) is taken into account [3.55]

$$\begin{aligned} E_{\text{att}}^{hkl} (\text{solvent modified}) \\ = E_{\text{att}}^{hkl} - [n_s E_{hkl}^i - N_A S_{hkl} \gamma_s] \times Z^{-1}, \end{aligned} \quad (3.34)$$

Z and N_A being the number of molecules in the unit cell and the Avogadro number, respectively. Expression (3.34) can be also easily adapted to the adsorption of an additive, treated as a medium, once the adhesion

energy of the solvent has been adequately replaced by that of the additive. This solvent-effect approach was successfully applied to the growth of the α -polymorph of glycine from aqueous solution, since a bi-univocal correspondence was found among the theoretical and experimentally observed F-faces. Moreover, this model explained as well the replacement of the most important {110} form of γ -aminobutyric acid in vacuo by the {120} form in water, and the flattening of the {001} form when a cationic or H-bonding additive is used [3.56].

The most complex and up-to-date method for predicting the growth morphology from solution was proposed by the Bennema school. Two interesting examples will be illustrated here.

In a first paper [3.57] it was shown that both 3-D and surface morphologies of tetragonal lysozyme crystals could be explained by a connected net analysis based on three different bond types corresponding to those used in the Monte Carlo growth simulation. Besides, the E_{att} of the different forms were estimated, along with their step energies. Furthermore, the significant β dependence of the relative growth rates of the {110} and the {101} forms, experimentally observed, was coherently explained on the basis of the multiple connected net analysis. More recently [3.58] a comparison was made between the E_{att} method and Monte Carlo simulations applied to all faces occurring in the growth morphology, with both approaches based on the connected net analysis. This was done considering that the E_{att} method cannot, intrinsically, take into account T , β , and growth mechanisms, while the simulation [3.59] can not only do this, but can also predict growth with or without the presence of a screw dislocation. The comparison was applied to solution growth of the monoclinic polymorph of paracetamol, using four different force fields [3.58]. It resulted that:

- The force field has only a small effect on the morphology obtained by the E_{att} method.
- The morphology so predicted does not resemble the experimentally ones for any of the β regimes.

Monte Carlo simulation gave different results, even under the limiting assumption that surface diffusion could be neglected: the {110}, {201}, and {100} forms have for all crystal graphs approximately the same growth curves, while all graphs show very different growth behaviors for the other two forms, {001} and {011}, owing to the differences of their step energies. Moreover, the {100} form is the theoretically fastest-growing form, according to the experimental observations. Finally, from the overall comparison between Monte Carlo simu-

lated and experimental morphologies, it emerged that the simulated results were poorer in form, even if the β effect was accounted for. This discrepancy is due to the {201} faces, which grow too slowly in the simulations and then assume too large an importance when compared with the other forms.

The Effect of Impurity Adsorption on the Theoretical Growth Shape

A large body of research on this topic is that carried out on NaCl-like crystals when specific ions are added to pure aqueous mother solutions. In the NaCl structure there are strong PBCs, in the equivalent $\langle 100 \rangle$ directions, determining the F-character of the cube- $\{100\}$ form. Other zigzag $\cdots \text{Na}^+ - \text{Cl}^- - \text{Na}^+ - \text{Cl}^- \cdots$ chains run along the $\langle 110 \rangle$ directions, within slices of thickness d_{111} , but they are polar chains and thus cannot be considered PBCs. Consequently, the {111} octahedron has K-character and is electrically unstable, being built by faces consisting of alternating planes containing either Na^+ or Cl^- ions. Stability can be achieved by removing 3/4 of the ions of the outermost layer and 1/4 of the subjacent one: thus, the new unit cell of the crystal, a cubic $4 \times [\text{Na}^+ \text{Cl}^-]$ octopole, has no dipole moment. Nonetheless, the *reconstructed octahedron maintains its K-character* and cannot appear either at equilibrium or in the theoretical growth shape of the crystal, owing to the too high values of $\gamma_{111}^{\text{NaCl}}$ and $E_{\text{att}}^{111(\text{NaCl})}$ with respect to $\gamma_{100}^{\text{NaCl}}$ and $E_{\text{att}}^{100(\text{NaCl})}$, respectively [3.60, 61]. Evidence of this behavior was shown by annealing {111} faces of NaCl crystals, near equilibrium with their vapor, and proving that they were structurally similar to those predicted by the reconstructed model [3.62].

A widely different situation emerges when NaCl-like crystals grow in solution in the presence of minor amounts of species such as Cd^{2+} , Mn^{2+} , Pb^{2+} , urea ($\text{CO}(\text{NH}_2)_2$), Mg^{2+} , and CO_3^{2-} . The most complete contribution on this subject is that of the Kern school [3.63–67]. Apart from the influence of β on the growth shape, Cd^{2+} is the most effective impurity, as even a small concentration gives rise to the habit change $\{100\} \rightarrow \{100\} + \{111\}$, as observed by optical microscopy. This change is not due to the random adsorption of Cd^{2+} ions on the {111} surfaces; it was attributed first to 2-D epitaxial layers of CdCl_2 , which can form matching the {111} surface lattice even if the mother solution is unsaturated with respect to the 3-D crystal phase of CdCl_2 [3.66]. Later on, and after measurements of adsorption isotherms, another interpretation was proposed [3.67]: the adsorption 2-D

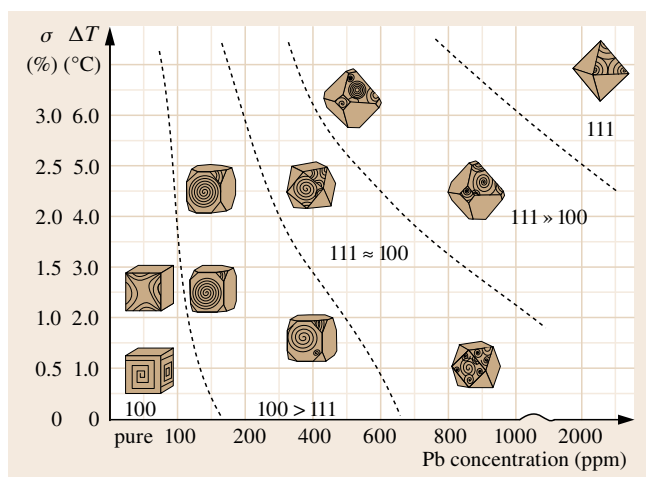

Fig. 3.14 Morphodrome showing the change $\{100\} \rightarrow \{100\} + \{111\}$ of crystal habit of KCl crystals with supersaturation excess ($\sigma = \beta - 1$) and impurity (Pb^{2+} ion) concentration. Surface patterns are also drawn (after [3.71])

epitaxial layer assumes the structure of the mixed salt $\text{CdCl}_2 \cdot 2\text{NaCl} \cdot 3\text{H}_2\text{O}$ once the isotherm has reached its saturation value. This hypothesis was supported by the finding, at supersaturation, of 3-D crystallites of the mixed salt epitaxially grown on $\{111\}$ surfaces. However, the existence of the 2-D epitaxial adsorption layer was not proved experimentally. More modern and recent research, based on optical observations, AFM measurements, and in situ surface x-ray diffraction [3.68–70] led to the conclusion that the polar $\{111\}$ surface should be stabilized by a mixed monolayer of Cd^{2+} (occupancy 0.25) and water (occupancy 0.75) in direct contact with the top Cl^- layers of $\{111\}$ NaCl underneath.

Summarizing, the evidence that emerges from this long-debated topic is that: when the surface of the growing crystal undergoes some intrinsic structural instability, such as surface polarity, and the growth medium contains some suitable impurities, *more or less ordered and layered structures form at the interface*, lending stability to the surface structure.

Since supersaturation plays a fundamental role in habit change, a sound and practical method was proposed [3.34] to represent the crystal habit as a function of both supersaturation (β) and impurity concentration. This drawing was called a *morphodrome*, as illustrated in Fig. 3.14, showing the changes of crystal habits of

KCl crystals with β and impurity (Pb^{2+} ion) concentration [3.71].

A behavior similar to that of NaCl-like crystals is shown by calcite (CaCO_3) crystals growing in the presence of Li^+ ions, which generate the $\{10\bar{1}4\} \rightarrow \{10\bar{1}4\} + \{0001\}$ morphological change [3.72]. Also in this case the formation of a 2-D epitaxial layer of the monoclinic Li_2CO_3 seems to be the most reasonable way of stabilizing the $\{0001\}$ form. In fact, AFM observations prove that lithium promotes the generation of quasiperiodic layer growth on the $\{0001\}$ surfaces ($\text{K} \rightarrow \text{F}$ character transition), while structural calculation indicates that Li^+ ions coming from the mother phase can perfectly take the place of calcium ions missing in the outermost reconstructed calcite layers. The credibility of this epitaxial model is enhanced by ab initio calculation [3.73] showing that the relaxed CO_3^{2-} ions, belonging to the d_{002} slice of Li_2CO_3 at the calcite/ Li_2CO_3 interface, entail the best coupling with the relaxed position of the outermost CO_3^{2-} ions of the reconstructed calcite crystal.

Certainly, the search for an epitaxial model for solution growth is most intriguing when one can both predict and interpret the effect of an impurity on the crystal habit, especially when the solvent may favor the formation of a structured crystal–solution interface. Nevertheless, there are other ways of assessing the impurity effects. One of these is to consider the modifications introduced by the impurity on the *energetics* of the elementary cell of the crystal in its outermost layer. This is the case for *disruptive tailor-made additives* [3.74], which are generally smaller than the host system but with a high degree of molecular similarity (e.g., benzamide/benzoic acid), which can adsorb on specific surface sites and thus influence the attachment energy value associated with the adsorption of subsequent growth layers. On the other hand, the *blocker type of molecular additive*, which is structurally similar but usually larger than the host material, has an end group which differs significantly and hence can be accepted at specific sites on some crystal faces. Thus, the end group (the blocker) prevents incoming molecules getting into their rightful positions at the surface. In fact, in the naphthalene–biphenyl host–additive system the E_{att} values of the different $\{hkl\}$ forms are selectively modified by the blocker additive. Steric repulsion resulting from the atoms of the blocker residing close to, or actually in, the same physical space in the crystal as atoms of the adjacent host molecules, both lowers the corre-

sponding E_{att} value and prevents host molecules from adsorbing, due to the blocking of surface sites [3.75]. Summarizing, the effects of solvent and impurities were

globally considered by calculating, through an ad hoc program, modified attachment energy terms, leading to simulated modified morphologies [3.76].

3.3 Factors Influencing the Crystal Habit

It is convenient to state some definitions. By *morphology* we mean the set of $\{hkl\}$ crystal forms occurring in a crystal independent of the surface areas, which is taken into consideration in the *crystal shape*. *Crystal habit* has to do with the dominant external appearance and is related to growth conditions. In the following only crystal habit is considered.

Crystals of the same phase can exhibit a great variety of crystal habits. This was one of the major difficulties in the beginning of crystal study and partly still remains, notwithstanding the enormous theoretical and experimental progress. This subject has both scientific and applied relevance. In many industrial sectors, crystal habit change is necessary to prevent crystal caking, filter crystal precipitates, obtain more convenient crystal products (in terms of shape, size, size repartition, purity, quality, etc.), simplify storage and package, etc. Empiricism played an important role in industrial crystallization in the past, but has been progressively supported and replaced by knowledge of crystal growth mechanisms and phenomenological rules.

Experiments show that crystal faces generally grow layer by layer, as already noticed by Niels Steensen. They move at different rates, and the fast-growing ones are destined to disappear. Therefore the habit of a crystal is determined by the faces having the slowest growth rates. Crystal habit may change either through the relative development of already existing $\{hkl\}$ forms or the appearance of new $\{h'k'l'\}$ forms.

The procedures to study the crystal habit change are well established: experimental crystal habits, grown from different solvents, are compared to the theoretical one, which may be obtained by calculations with different available methods (BFDH, PBC-attachment energy-connected nets, IS analysis) or by growing the crystal from the vapor phase, in which the fluid–solid and fluid–fluid interactions are negligible. Indeed, a complete study should involve the growth kinetics of each face, in order to determine its growth mechanism and the roles of the specific solvent and/or impurity.

As the crystal–solution interface is the critical site for face growth and crystal habit, all available approaches are applied to the study of this surface. A list is given in Chap. 5. The factors influencing the crystal habit are numerous and have different effects, which explains the great habit variability. They are usually classified into two main categories:

1. Internal factors: the crystal structure, on which the surface structures (i. e., the profiles) of the faces depend, and crystal defects
2. External factors, which act from the *outside*: supersaturation, the nature of the solvent, solution composition, impurities, physical conditions (temperature, solution flow, electric and magnetic fields, microgravity, ultrasound, etc.).

There are also mixed factors, such as the free energy of crystal surfaces and edges, which depend on both crystal surface structure (an internal factor) and the growth environment (an external factor). The most important ones are considered separately in the following, even if it is necessary to look at the crystal growth as a whole, complex process, in which a change in one parameter (temperature, solubility, solvent, supersaturation) influences all the others, so that they together affect crystal growth and habit. Let us consider a polymorphic system made of two phases: A and B. Changing, for example, the solvent at constant temperature and concentration, both surface free energy (γ) and supersaturation (β) are changed. If these variations are small, changes concern only the crystal habit of one polymorph (e.g., A). If the variations are large, the nucleation frequencies of the two polymorphs can be so affected that a change in crystal phase occurs and the B polymorph may nucleate. The same considerations apply to the temperature change, which promotes variations in solubility, surface tension, and supersaturation, especially in highly soluble compounds.

3.4 Surface Structure

Each crystal face has a specific surface structure, which controls its growth mechanism. As the crystal habit is limited by the faces having the slowest growth rates, i. e., the F-faces, in the following only the F-faces will be considered. The surface of an F-face is not perfectly flat and smooth, but is covered by steps and other features (hillocks), which condition the growth rate of the face and its development. Indeed, layer growth is possible when the edge energy of a 2-D nucleus is positive [3.2, 27]. The growing steps may be inclined with respect to the surface, forming an acute and obtuse angle which advance at two different velocities, as observed on the {001} face of monoclinic paraffins [3.77]. Surface features (dislocation activity, step bunching) and parameters (step speed, hillock slope) are sensitive to supersaturation and impurities and behave in different ways at low and high supersaturation, with linear and nonlinear dependence [3.78]. Connected to these factors is the morphological instability of steps and surfaces, which is enhanced or prevented by shear flow, depending on the flow direction [3.78–83]. Great theoretical, experimental, and technical contributions to the study of surface phenomena are due to Russian [3.78–81], Dutch [3.82–85], and Japanese [3.15, 16, 86] groups as well as to other researchers [3.87–92] and to those quoted in all these papers. Surface phenomena and morphology have been recently reviewed [3.15–18]. AFM has enormously enlarged this research field, as it allows the observation of the surface features of the growing faces both ex situ and in situ at a molecular level. This new technique is providing a growing number of new data and observations, and at the same time renewing and stimulating interest in surface phenomena and processes, especially step kinetics, impurity effects, edge fluctuations, and stability.

3.4.1 The α -Factor and the Roughening Transition

In Sect. 3.2.2 the concept of α -factor was introduced as a measure of the roughness of a surface and its probable growth mechanism. Knowledge of α is mostly useful; however, it may be not sufficient, as noticed for several alkanes, which show the same α value in different solvents, yet have different growth mechanisms [3.93], and also for the {010} and {001} faces of succinic acid grown from water and isopropyl alcohol (IPA). Each face has the same α -value in both solvents; nevertheless the growth rates are appreciably lower in IPA

than in water, owing to different efficiency of hydrogen bonding with IPA and water molecules [3.45]. With increasing temperature (3.32a) the α -factor decreases and may reach values lower than 3.2. In that case the surface loses its flatness, becomes rough, and grows by a continuous mechanism. This transition occurs at a definite roughening temperature which is characteristic for each face. For example, the {110} faces of paraffin $C_{23}H_{48}$ growing from hexane has a roughening temperature of $T^R = 10.20 \pm 0.5$. Below T^R the faces are straight, whereas above it they become rounded even if supersaturation is very low [3.11].

3.4.2 Kinetic Roughening

Beside thermal roughening, a surface may undergo kinetic roughening, which occurs below the roughening temperature when the supersaturation exceeds a critical value. In this case the sticking fraction on the surface is so high and the critical two-dimensional nucleus so small that the surface becomes rough and grows through a continuous mechanism. This behavior was observed on the {100} faces of NaCl in aqueous solutions [3.94] and in naphthalene crystals, which become fully rounded when σ attains 1.47% in toluene solvent. The same does not occur with hexane, due to structural dissimilarity of hexane molecules with respect to naphthalene [3.11]. Four criteria used to identify the beginning of kinetic roughening have been studied by Monte Carlo simulations on a Kossel (100) surface, leading to different values of the critical driving force [3.95].

3.4.3 Polar Crystals

In polar crystals a d_{hkl} slice may present a dipole moment. In that case a correction term, E_{corr} , should be added to the expression for E_{att} to maintain the value of E_{cr} constant [3.35, 36] (Sect. 3.2.2, (3.29)), i. e.,

$$E_{\text{cr}} = E_{\text{att}} + E_{\text{slice}} + E_{\text{corr}}, \quad (3.35)$$

with $E_{\text{corr}} = 2\pi\mu^2/V$, where V is the volume of the primitive cell and μ the dipolar moment of the slice (per formula unit) [3.96]. The surfaces of the two opposite faces (hkl) and ($\bar{h}\bar{k}\bar{l}$), being structurally complementary, interact in a selective way with the solvent and impurity molecules. The final result is a different development of these faces, which may lead to the occurrence of only one form, as observed in the case

of the $(011)/(0\bar{1}\bar{1})$ faces of $\text{N}(\text{C}_2\text{H}_5)_4\text{I}$ [3.97] and the $\{100\}$, $\{\bar{1}\bar{1}\bar{1}\}$, $\{0\bar{1}\bar{1}\}$, and $\{1\bar{1}0\}$ faces of $\text{ASO}_3 \cdot 6\text{H}_2\text{O}$ ($\text{A} = \text{Co}^{2+}$, Ni^{2+} , Mg^{2+}). In this case the water molecules are selectively adsorbed on the opposite faces since they have a different surface distribution of sulfite ions and $\text{A}(\text{H}_2\text{O})_6^{2+}$ groups [3.98]. The structural differences can be so great that the two opposite faces may grow with a different mechanism, as experimentally shown for the $\{110\}$ and $\{1\bar{1}0\}$ faces of sucrose crystals: the former by volume diffusion with $\Delta G_{\text{cr}} = 10 \text{ kcal/mol}$ and the latter by surface diffusion with $\Delta G_{\text{cr}} = 21 \text{ kcal/mol}$ [3.54].

3.4.4 Looking at Surfaces with AFM

AFM is becoming a routine technique in growth laboratories. Most experiments are carried out in static conditions, some in the dynamic regime. One of the most studied compounds, besides proteins, is calcite. The $\{10\bar{1}4\}$ cleavage form grows via monomolecular

steps, which are differently affected by anion and cation impurities [3.99]. AFM has been used to assess the stability of the $\{111\}$ faces of NaCl in pure and impure aqueous solutions and to attempt to solve the problem of surface reconstruction [3.70, 71]. Through AFM investigation of the $\{100\}$ faces of potassium dihydrogen phosphate KDP, the dependence of macrosteps and hillocks on β was measured and new values of the step edge energy, kinetic coefficients, and activation energies for the step motion were calculated, confirming the models of Chernov and van der Eerden and Müller-Krumbhaar [3.100]. In studying the influence of organic dyes on potassium sulfate the link between the surface features at the nanoscale level and the macroscopic habit change was proved [3.101]. To sum up, AFM analysis enables local details of surface structure and their evolution in real time to be captured, yielding a lot of information, but has the drawback that it does not permit large-scale views of the face, so it has to be integrated with other instrumental (optical and x-ray) techniques.

3.5 Crystal Defects

Defects easily and usually occur in crystals. It is not necessary to emphasize the role of screw dislocations in crystal growth. As concerns edge dislocations, they could affect the growth rate since a strain energy is associated with the Burgers vector and then increases the growth rate. Combined research on the effect of dislocations on crystal growth with in situ x-ray topography was done on ammonium dihydrogen phosphate ADP crystal [3.78]. Edge dislocations were proved to be inactive in step generation on the ADP (010) face, whereas screw dislocations were active. When a dislocation line emerges on a given (hkl) F-face, the face grows at higher rate than the other equivalent ones and therefore decreases its morphological importance with respect to the others. In crystals with cubic symmetry the habit may change from cubic to tetragonal prism or square tablet. When a screw dislocation crosses an edge, it becomes inactive [3.78]. Contrary to the current opinion that increasing the growth rate leads to a higher defect density, as supported by Monte Carlo simulations [3.102], large crystals with a high de-

gree of structural perfection can be obtained with the method of *rapid growth*, which consists of overheating a supersaturated solution, inserting a seed conveniently shaped, and strongly stirring the solution submitted to a temperature gradient. The method, applied for the first time in the 1990s, allows the preparation in short time of very large crystals of technologically important compounds such as KDP and deuterated potassium dihydrogen phosphate DKDP up to 90 cm long and nearly free of dislocations. The crystal habit, bounded by $\{101\}$ and/or $\{110\}$ faces, may be controlled by creating dislocation structures during the seed regeneration and changing the seed orientation [3.103, 104]. Crystals grown with the traditional method at low temperature are smaller and rich in striations and dislocations, originated by liquid inclusions. Large perfect crystals can also be quickly grown from highly concentrated boiling water solutions. The method has been successfully applied to some compounds, such as KDP, $\text{Pb}(\text{NO}_3)_2$, and $\text{K}_2\text{Cr}_2\text{O}_7$. Due to the high growth rates and β values, the crystal habit becomes equidimensional [3.105].

3.6 Supersaturation – Growth Kinetics

The effect of supersaturation on growth morphology is well known, but not yet well understood, since

when a system becomes supersaturated, other parameters change in turn, especially in solutions of poorly

soluble compounds (phosphates, sulfates, etc.). In this case a change in β involves variations in solution composition, chemical species, and related phenomena (ion coordination, diffusion, etc.) [3.106]. First of all, β is important in controlling both the size and shape of the 3-D and 2-D critical nucleus (3.11) and in determining the growth kinetics. The growth rates of S- and K-faces are linear functions of β . For an F-face the dependence is more complicated, being related to the growth mechanism. The dependence law for R_{hkl} versus β may be parabolic, linear (in the case of a spiral mechanism), exponential (for two-dimensional nucleation) or again linear (when the face grows by a continuous mechanism at high β values). Spectacular habit changes are observed with increasing β . At high β values, first hopper crystals, then twins, then dendrites, and finally spherulites may form [3.107]. All possible cases are gathered in the diagram of R_{hkl} versus σ proposed by Sunagawa [3.108] (Chap. 5). The basic kinetic laws for growth controlled by surface diffusion, i.e., in the kinetic regime, are summarized here.

3.6.1 Growth Laws

For the spiral mechanism (BCF theory [3.7]) the growth rate of a (hkl) face is given by

$$R_{hkl} = \frac{v_{\infty} d_{hkl}}{y_0}, \quad (3.36)$$

where v_{∞} is the step velocity, d_{hkl} is the interplanar distance, and y_0 is the equidistance between the spiral steps. The step velocity for growth from solution [3.109] is given by

$$v_{\infty} = \beta_k c_0 D_s n_{s0} f_0 \frac{\sigma}{x_s} \tanh \frac{y_0}{2x_s}, \quad (3.37)$$

where β_k is a retarding factor for the entry of a growth unit (GU) in the kink, $c_0 = \frac{x_s}{x_0} \ln(2x_s/(1.78a))$ valid for $x_s \ll x_0$ (when $x_s \gg x_0$, $c_0 = 1$), x_s is the mean displacement of the GUs on the surface, x_0 is the mean distance between kinks in the steps, D_s is the diffusion constant of GUs in the adsorption layer, n_{s0} is the number of GUs in the adsorption layer per cm^2 at equilibrium, f_0 is the area of one GU on the surface, and $\sigma = (X - X_s)/X_s$ is the relative supersaturation (where X and X_s are the actual and equilibrium molar fraction, respectively). The step equidistance y_0 is given for low supersaturation by

$$y_0 = fr^* = \frac{f \rho a}{k_B T \ln \beta} \cong \frac{f \rho a}{k_B T \sigma}, \quad (3.38)$$

being f a shape factor, r^* the critical radius of the 2-D nucleus, ρ the edge free energy (erg/cm), and a the

shortest distance between GUs in the crystal. The relationship is simplified if the supersaturation β is low, in which case $\ln \beta \cong \beta - 1 = \sigma$.

Then (3.36) may be written as

$$R_{hkl} = C \frac{\sigma^2}{\sigma_1} \tanh \frac{\sigma_1}{\sigma}, \quad (3.39)$$

where C and σ_1 are constants:

$$C = \frac{\beta_k c_0 D_s n_{s0} \Omega}{x_s^2},$$

$$\sigma_1 = \frac{9.5 \rho a}{\varepsilon k_B T x_s},$$

where Ω is the volume of growth unit and ε is related to the number of interacting growth spirals.

When $\sigma \ll \sigma_1$ (i.e. $y_0 \gg x_s$)

$$R = C \frac{\sigma^2}{\sigma_1} \quad (\text{parabolic law}),$$

When $\sigma \gg \sigma_1$ (i.e. $y_0 \ll x_s$)

$$R = C \sigma \quad (\text{linear law}).$$

Other relationships were found by Chernov for direct integration in the kink [3.110] and by Gilmer et al. [3.111] for coupled volume and surface diffusion.

For the two-dimensional nucleation mechanism

$$\text{mononuclear mechanism } R_{hkl} = K_m J_{2D}, \quad (3.40)$$

$$\text{polynuclear mechanism } R_{hkl} = K_p v^{2/3} J_{2D}^{1/3}, \quad (3.41)$$

where K_m and K_p are the kinetic constants for the two types of mechanism, v is the step speed, J_{2D} is the 2-D nucleation frequency, which is given by

$$J_{2D} = K \exp\left(-\frac{f \rho^2 a^2}{(k_B T)^2 \ln \beta}\right), \quad (3.42)$$

where K and f are the kinetic and shape factors, respectively. Equation (3.42), formerly derived for growth from vapor state, is usually applied to growth from solution.

There is also a general empirical law

$$R_{hkl} = K' \sigma^n, \quad (3.43)$$

where K' is a kinetic temperature-dependent constant; the value of n is related to the mechanism.

3.6.2 Some Experimental Results

As $R_F < R_S < R_K$, in the growth form at a given β only F-faces can occur, although not necessarily all of

Fig. 3.15 Crossover of the growth rates versus thermodynamic supersaturation for the {110} and {101} faces of tetragonal lysozyme with change in crystal habit (after [3.57])

them. The faces of the same crystal may show a different dependence of R_{hkl} on β and then a crystal habit change can occur. The first static observations were made on NaCl, KCl, CsCl, KI, and many other ionic salts. When a crystal habit is made of F-faces, a higher critical supersaturation is needed for the S- or K-faces to appear [3.63, 112] (Sect. 3.2.2). When an F-face is replaced by another F-face at high supersaturation, the change is progressive. Kinetic measurements of crystal growth reveal that in most cases there is a supersaturation *dead zone* in which no growth occurs, and a critical supersaturation β^* should be reached for growth to start. Changes in relative face size and crystal habit are usually observed with increasing β [3.47, 53]. In *n*-paraffins the growth rate was found to be dependent also on the platelet thickness [3.93]. When a crossover in the relative growth rates of faces occurs, even radi-

cal changes in morphology are observed, as in the case of γ -aminobutyric acid [3.113] and lysozyme crystals (Fig. 3.15) [3.57, 114].

To explain the habit change, a variation in the crystal-solvent interaction is admitted, as for NaCl, CsCl, $M(H_2O)_6 \cdot SiF_6$, and CaF_2 [3.42]. In other cases the effect of supersaturation is attributed to the desolvation kinetics of the solute, as shown for KI, KBr, and KCl [3.115].

Supersaturation also causes changes in surface features, as seen on the {100} faces of $NH_4H_2PO_4$ (ADP), where there are no growth layers below a given β , and elliptical and then parallel layers appear with increasing β [3.116]. Supersaturation affects the activity of dislocation source [3.78]. The intensive studies of surfaces of ADP, KDP, and DKDP reveal that the step speeds on these faces and the hillock slopes may be nonlinear functions of β [3.78, 117]. This nonlinearity has been explained in terms of a complex dislocation step source [3.78], impurity adsorption [3.118], and the generation of kinks at growth steps [3.119]. Not only the step rates but also the kinetic coefficients can depend on β , which enhances the morphological instability [3.87]. It should be noted that, even in the kinetic regime, supersaturation is not constant along the growing face [3.78]. Small fluctuations in β may cause rapid change in the evolution of faces forming small interfacial angles, with the disappearance and reappearance of faces, as observed with potassium dichromate [3.120].

High supersaturation can determine phase transition, as shown in polymorph systems such as calcium carbonate, L-glutamic acid, and L-histidine [3.121]. Interest is also practical: from 2-propanol solutions it is possible through supersaturation to isolate the stable form of stavudine, an antiviral drug used for the treatment of human immunodeficiency virus-acquired immunodeficiency syndrome (HIV-AIDS) [3.122]. However resorting to high supersaturation in order to change the crystal habit is rarely used in industrial crystallization, as there is a risk of unwanted nucleation.

3.7 Solvent

Research into solvent effects on crystal growth and habit is relatively recent. In the years 1940–1967 a few studies were published, as summarized in two surveys papers [3.44, 123]. In the 1960s the first interpretations were geometric-structural [3.124]. The effect of the solvent in determining the mechanism of crystal

growth was evaluated through the entropic α -factor and the growth kinetics [3.44, 123]. Since then, interest in this topic has been increasing, also due to the mounting needs of industrial crystallization. Research was then successfully extended to tailor-made additives [3.14, 125] (see also Sect. 3.2.3). Molecu-

lar dynamics (MD) simulations are also extensively applied to study the solvent–surface interaction. The solvent itself acts as an impurity; however, due to its importance (e.g., concentration), it is treated separately.

3.7.1 Choice of Solvent

The first essential step for crystallization is the choice of solvent. Knowledge of solubility and of its change with temperature is required. The most common solvent is water, which exerts its influence even in traces in the vapor and liquid phase. When lead molybdate is grown in dry air, it crystallizes as needles, but as platelets in moisturized air [3.127]. Small amounts of water added to organic solvents markedly increase the yield and growth rate of the target polymorph of pharmaceutical compounds [3.128]. Growth in aqueous systems is a complex process. Water molecules are coordinated by cations and anions in solution; in addition, they can be

selectively adsorbed at the different sites on the growing faces (Fig. 3.16) [3.109, 126].

Dehydration and desolvation should then occur, besides diffusion, involving the respective activation energies [3.109]. It should be noted that solvent molecules (and possible impurities) are also involved in surface adsorption processes, with an ensuing competition between the corresponding energies (or relaxation times) of growth units. The bonds engaged may be ionic, hydrogen bond, and van der Waals, with energies of about 15 kcal/mol (for the $\text{H}_2\text{O}-\text{Na}^+$ bond), 5 kcal/mol in organic solutions with hydrogen bonds, whereas for the van der Waals bond the strength is one or more orders of magnitude smaller than that of the ionic one. Many other solvents, mostly organic and tailor-made, are nowadays used in the chemical industry. They differ from water in some molecular properties (dielectric constant, dipole moment, size, etc.) and are classified into three main classes: protic (hydrogen donors, e.g., methanol), dipolar aprotic (e.g., acetonitrile), and non-polar aprotic (e.g., hexane) [3.129].

3.7.2 Change of Solvent

Use is often made of different solvents in crystal growth. Solvent change has several correlated effects (on solubility and supersaturation, interactions with solute and crystal faces, surface free energy, etc.), and modifying the α -factor may change the growth mechanism. If a compound is grown from two different solvents, A and B, there are two values of α , which are related by [3.130]

$$\begin{aligned}\alpha_A &= \alpha_B + 4(\Phi_{B,\text{sf}} - \Phi_{A,\text{sf}})/(k_B T) \\ &\quad + 2(\Phi_{A,\text{ff}} - \Phi_{B,\text{ff}})/(k_B T) \\ &\approx \alpha_B + 4(\Phi_{B,\text{sf}} - \Phi_{A,\text{sf}})/(k_B T) .\end{aligned}\quad (3.44)$$

Let $\Phi_{A,\text{ff}} \approx \Phi_{B,\text{ff}}$. If the solute–solvent interaction energy $\Phi_{B,\text{sf}}$ is higher than $\Phi_{A,\text{sf}}$, then $\alpha_A > \alpha_B$. For example, the {110} faces of hexamethylene tetramine (HMT) grown in aqueous solution show $\alpha < 2.5$, whereas in ethanolic solutions the value is $\alpha = 3.2\text{--}5.4$ [3.130]. The growth mechanisms predicted by these values were confirmed by the growth kinetics [3.131]. Changing the solvent allows one to understand the role of the solvents and the bonds involved, as shown by *m*-nitroaniline. Grown from a nonpolar solvent, the crystal habit matches the theoretical one, based on the sole van der Waals bonds, whereas in polar solvents the electrostatic interactions play a great role [3.132]. By comparing steroid crystals grown from acetone and

Fig. 3.16a,b The events leading to crystal growth: diffusion in the volume, on the surface, along the step, to the kink with integration; desolvation; and desorption. To each of these processes corresponds an activation energy of different magnitude (after [3.126])

methanol solutions and performing MD simulations of the solvent–surface interactions, it is found that the contributions of Coulomb and van der Waals bonds are more important than hydrogen bonding in determining the crystals habit [3.133]. Solvents may affect surface roughness [3.129] and the roughening transition of faces, with a change in the transition order too [3.134]. Mixtures of solvents are often used. They can show higher solubility than separate solvents, as happens with L-pyrogutamic acid, which is more soluble in a water–ethanol mixture than in pure water or pure methanol, with a strong change of crystal habit [3.135]. On the other hand, mixtures of water and isopropoxethanol, in which NaNO_3 is less soluble, do not affect the shape of the NaNO_3 crystals [3.136], whilst adding water to an ethanol–water solution saturated with benzoic acid reduces the solubility of the latter and causes its crystallization with habit change (the drowning-out technique) [3.137]. Solvent can also stabilize polymorphs, as shown with CaCO_3 precipitated from water or ethanol solutions [3.138], and promote the formation of twins as well [3.125].

3.7.3 Solvent–Solute

Molecules of solvent and solute always interact, affecting the growth kinetics according to the energy involved. The interaction is more pronounced in supersaturated solutions [3.106]. In aqueous solutions of ionic salts, solute clusters which have the lattice structure of the crystal surface can form [3.139]. In aqueous solutions of hexamethylene tetramine (HMT), each HMT molecule coordinates four water molecules, whereas in alcoholic solutions there is no coordination, with consequences for the growth mechanisms [3.123]. Solute dimers may form, and tetramers, octamers, and even larger -mers were also detected in lysozyme solutions at high supersaturation [3.57]. The strong morphological difference of alizarin crystals grown from alcoholic and other organic solvents is attributed to the partial deprotonation of the alizarin molecules occurring in alcohol solutions, which blocks the needle growth of the side faces, leading to a totally different habit [3.140].

3.7.4 Solvent–Crystal Surface

The approach to the problem of the role played by solvent–crystal interactions is different according to the system being studied and theoretical assumptions.

A relevant role is attributed to the α -factor [3.123, 130] with some reservations on its general validity [3.129]. Another way of looking at the solvent–crystal interactions is by considering adsorption of solvent molecules on the surface sites, as shown between the [010] PBCs on {101} faces of sucrose [3.47]. The role of solvents in terms of surface roughening and surface adsorption on crystal morphology is reviewed in [3.44]. A protic solvent can determine both the polymorph and crystal habit, as shown for stavudine, in the molecule of which one N atom is a very strong H-bonding donor and two O atoms are strong H-bonding acceptors. The crystal surfaces interact in different ways with polar and nonpolar solvents [3.122]. The effect of α -butyrolactone as a solvent on cyclotrimethylene trinitramine (RDX) crystals has been explained by invoking a third region between the crystal and solution bulk, i.e., a boundary layer. MD simulations show that the average energy of solvent molecules near the surface is higher than the average energy of the same molecules in the bulk, therefore the potential energy change per unit area can be chosen as a good parameter to use in explaining solvent effects on the crystal habit [3.141].

3.7.5 Mechanisms of Action

Solvent molecules are temporally adsorbed at the various sites of surface: ledges, steps, and kinks, with different lifetimes, which has an effect on growth rates. The formation of surface complexes was suggested for $\text{Hg}(\text{CN})_2$ crystals grown from methanol [3.142]. As solutions of *n*-paraffins in petrol ether behave as a melt, a structural model was proposed, which considers the paraffin crystal as a Kossel crystal and the solvent molecules as in the Ising model, so that they easily adhere by adsorption to steps [3.143]. In polar crystals the complementary forms $\{hkl\}$ and $\{\bar{h}\bar{k}\bar{l}\}$ exhibiting different surface structures selectively interact with the solvent molecules, as in $\text{N}(\text{C}_2\text{H}_5)_4\text{I}$ crystals grown from four solvents, which being differently adsorbed onto {011} and $\{0\bar{1}\bar{1}\}$ faces, invert the morphological importance of these faces [3.97]. The morphological difference is relevant for industrial crystallization: the analgesic ibuprofen grown from ethanol shows a pseudohexagonal tabular habit but thin elongated platelets from ethyl acetate, owing to the interactions between ethyl acetate molecules and ibuprofen carboxylic groups emerging at the surface of {100} and {002} faces of the crystal [3.144].

3.8 Impurities

The literature dealing with the effects of impurities on growth kinetics and crystal habit is enormous and increasing. After the publication in 1951 of the BCF theory [3.7] and of Buckley's book on crystal growth [3.145], the advance has been impressive. Fourteen years later a whole book was devoted to the relationships between adsorption, crystal growth, and morphology [3.146]. In Russia this topic has been widely studied, as evident from the series of volumes on crystal growth. The role of impurity is also a specific object of the proceedings of periodic symposia on industrial crystallization. Indeed, a strong impulse to research in this field is provided by mounting industrial demands. Many cases are given and discussed in some review papers [3.83, 147–149] and a summary with a nearly exhaustive literature is found in Sangwal's monograph [3.150]. In recent years, interest has focused on additives and other large molecules used as habit modifiers. A synthetic view is tentatively presented in the following. Admitting a hydrodynamic regime, the role of volume diffusion is neglected as impurities only influence the surface processes.

3.8.1 The Main Factors

Impurities influence both thermodynamic and kinetic factors. Addition of an impurity to a solution may change the surface free energy γ , the edge free energy ρ , and the solubility. Even if an increase of average surface energy is possible, it is usually admitted that ρ decreases with the concentration of the adsorbed impurity C_i . By assuming a Langmuir-type isotherm and equilibrium between the impurities adsorbed on the step and in the bulk, the resulting edge free energy (expressed in ergs, for the sake of simplicity) is given by [3.151]

$$\rho_i = \rho - k_B T \ln C_i. \quad (3.45)$$

Similarly, a positive adsorption produces a reduction in the specific free surface energy. It follows that, since ρ_i decreases with impurity concentration C_i , the growth rate of the face should increase.

The effect on solubility depends on C_i . If C_i is low or very low, of the order of ppm, the influence on solubility is negligible. If C_i is higher, of the order of mg/l or g/l, the solubility may change. In the case of solubility increase, the resulting effect is usually an increase in step velocity and the growth rate of faces [3.150]. Solubility and growth rate of ionic crystals may be increased by changing the pH or increasing the ionic strength

through addition of soluble salts, e.g., adding NaCl to $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ solutions [3.151].

The growth rate depends on the kinetic constant C (3.39) and the step velocity v (3.37). Impurities adsorbed on the surface will cause a decrease of C and hinder the advances of steps by mechanisms that depend on the adsorption site. The retardation factor (3.37) of the steps becomes [3.83]

$$\beta_{\text{st}} \cong \beta_{\text{st}}^0 \left(1 - \frac{4d}{(\kappa^*)^2} \right). \quad (3.46)$$

where β_{st}^0 is the retardation factor without adsorption at the step, d is the density of adsorbed impurity (cm^{-2}), and κ^* the critical curvature of the step (cm^{-1}).

As a general result, the growth rate is decreased.

Impurities may therefore have two opposite effects on crystal growth. The final result depends on the supersaturation and impurity concentration, as shown in the classical experiment of $\text{Pb}(\text{NO}_3)_2$ grown in the presence of methyl blue [3.150]. The increase of the growth rate at low supersaturation and low impurity concentration (the so-called catalytic effect) is attributed to the prevailing thermodynamic factor and a low density of kinks. At higher impurity concentration the resulting effect is a decrease of growth rate due to the dominance of kinetic factors. Similar behaviors were found in other cases [3.150].

3.8.2 Kinetic Models

Various models have been proposed to relate the step velocity to the effect of impurity adsorption. One of the first contributions is due to Bliznakow [3.152], who assumes that impurities are adsorbed on some of the active sites on the surface and derives a quantitative relationship between the step velocity and the kink site adsorption

$$v = v_0 - (v_0 - v_m)\theta_{\text{eq}}, \quad (3.47)$$

in which v_0 is the step velocity without adsorption in the kink; $\theta_{\text{eq}} \leq 1$ is the coverage degree, in impurity, of the surface, and v_m is the limiting step velocity in impure solution, when all the surface is covered by impurities (i.e., $\theta_{\text{eq}} = 1$). If a Langmuir isotherm is valid, then

$$v = v_0 - (v_0 - v_m) \frac{KC_i}{(1 + KC_i)}. \quad (3.48)$$

The model was satisfactorily applied to experiments reported by the same author and others [3.146] chiefly on

inorganic compounds and confirmed by curves of R versus C_i and the heat of adsorption measured at different temperatures [3.112].

Cabrera and Vermilyea (CV) [3.153] proposed a different model, in which the impurities are assumed to be immobile, adsorbed on ledges ahead of steps, where they form a two-dimensional (2-D) lattice. The steps move with average velocity v

$$v = v_0[1 - 2r^*/(d^{-1/2})]^{1/2}, \quad (3.49)$$

where r^* is the critical radius of the 2-D nucleus, and d is the average density of impurities, corresponding to a mean distance $s = d^{-1/2}$. The density of impurities d can also be expressed by the coverage degree of impurity (θ) times the maximum number (n_{\max}) of sites available for adsorption per unit area: $d = n_{\max}\theta$. From (3.49) it follows that when $s < 2r^*$, the step will stop; when $s > 2r^*$, it squeezes between the two adjacent impurities. At equilibrium between impurities adsorbed on the surface and solution, and if the coverage degree θ is given by a Langmuir isotherm, then

$$\theta = \frac{KC_i}{1 + KC_i}, \quad (3.50)$$

where K is the Langmuir constant. If $v \propto R_{hkl}$ and introducing the relative growth rate η , we have

$$\eta = \frac{v}{v_0} = \frac{R_{hkl}}{R_0}. \quad (3.51)$$

Rearranging (3.49)

$$\frac{1}{(1 - \eta^2)^2} = \frac{1}{4(r^*)^2 n_{\max}} + \frac{1}{4(r^*)^2 n_{\max} K} \frac{1}{C_i}. \quad (3.52)$$

If the CV model is valid, then the previous relation should be satisfied and allows one to obtain n_{\max} .

Since r^* is related to the critical supersaturation β^* (3.38), when $KC_i \gg 1$ (i.e. $\theta \rightarrow 1$), then

$$\frac{1}{(\ln \sigma^*)^2} = \frac{1}{(\ln \sigma_{\max}^*)^2} \left(1 + \frac{1}{K_1 C_i} \right). \quad (3.53)$$

When $KC_i \ll 1$, then

$$\ln \sigma^* = \ln \sigma_{\max}^* (KC_i)^{1/2}, \quad (3.54)$$

i.e., the critical σ^* necessary for a step to move increases with increasing C_i , which has been experimentally confirmed.

The validity of the CV mechanism has been verified in many experiments, mainly with organic impurities

and tailor-made additives, for example, in the growth of $C_{36}H_{74}$ from petroleum ether [3.93] and also in the growth of {101} faces of ADP under low supersaturation [3.118]. It may happen that strongly bound impurities may become incorporated in the crystal.

Sears [3.154], observing that 10^{-5} – 10^{-6} molal concentration of FeF_3 was sufficient to poison LiF in aqueous solution, postulated a complete monostep adsorption at the growth steps. He calculated the fractional change of 2-D nucleation rate, which for low step coverage is proportional to the C_i change, and recognized that two opposite effects operate, one tending to increase the growth rate, the other to decrease it.

Albon and Dunning [3.155], studying the growth of sucrose in the presence of raffinose, admit adsorption of impurity at kinks, which lowers the step rate. When the impurity distance is less than the diameter d^* of the critical nucleus (measured as an integer number of molecular spacings), the advancing step is blocked. If $p = (1 - C_i)$ is the probability of finding a free site along a step, then the step speed is given by

$$v = v_0[d^* - (1 - C_i)d^* + (1 - C_i)](1 - C_i)^{d^*}. \quad (3.55)$$

This model gives also a good description of the effects of Cr^{3+} on the growth of the {100} faces of ADP for $C_i > 1.0 \times 10^{-2}$ kg/m³ [3.156].

Davey and Mullin [3.91] assumed that the rate-determining process is the surface diffusion, which is reduced by impurities absorbed on the ledge, and that the number of absorbed growth units is proportional to the fraction of free surface sites at equilibrium $n_i = n(1 - \theta)$. They derived the relation

$$v/v_0 = 1 - \theta_{eq}. \quad (3.56)$$

By expressing θ_{eq} in terms of Langmuir isotherm, the equation becomes

$$\frac{v_0}{v_0 - v} = 1 + \frac{1}{KC_i}. \quad (3.57)$$

This relation was shown to be valid, for example, for layer velocities in the [001] direction for the {100} faces of ADP in the presence of some ppm of $AlCl_3$, $FeCl_3$, and $CrCl_3$.

Since complete coverage ($\theta_{eq} = 1$) is not a necessary condition to stop crystal growth, *Kubota and Mullin (KM)* [3.157, 158] introduced in the Davey–Mullin equation an effectiveness factor α given by

$$\alpha = \frac{r^*}{L} = \frac{\rho a}{k_B T \sigma L}, \quad (3.58)$$

where L is the distance between two adsorption sites and a is the surface area of a growth unit. It follows that, depending on the ratio r^*/L , the factor α may be greater than, equal to, or less than 1. In their model a linear arrangement of adsorption sites is assumed to occur along the step, so that one-dimensional (1-D) coverage is combined with an adsorption isotherm. So we have

$$v/v_0 = 1 - a\theta_{\text{eq}}. \quad (3.59)$$

Relating the relative velocity η to C_i by a Langmuir isotherm, we have

$$\frac{1}{1-\eta} = \frac{1}{\alpha K} \frac{1}{C_i} + \frac{1}{\alpha}. \quad (3.60)$$

From this relationship it is possible to evaluate the critical supersaturation necessary to overcome the dead zone

$$\beta^* = \frac{\rho \alpha K C_i}{k_B T L (1 + K C_i)}, \quad (3.61)$$

which can be rearranged as: $1/\beta^* = (C_1/C_i) + C_2$ (where C_1 and C_2 are two constants) [3.158].

The authors provide a number of examples, drawn from the literature, of the validity of their model for growth systems showing different α effectiveness factors [3.157]. The KM model was successively applied to crystal growth of other systems. Very recently, in studying the growth kinetics of the four main F-faces of sucrose in the presence of raffinose, both CV and KM models associated with Langmuir isotherms were tested. The agreement was better with the KM model than with CV, which means that adsorption occurs at kink sites and a spiral growth mechanism operates. The α effectiveness coefficient seems to be a very good parameter to predict the raffinose effects [3.159].

3.8.3 Adsorption Sites

Impurities act through adsorption, as apparent from the above kinetics models, onto the crystal surfaces, at steps and kinks. Adsorption occurs in this order, but only one process is considered determinant in the reaction path. They can be distinguished on the basis of some parameters (adsorption heat, activation energy, lifetime of the adsorbed state). A detailed description of adsorption at the three kinds of growth sites is given in some surveys papers [3.150, 160, 161]. The overall effect on the crystal habit depends on the effect on growth rates of faces.

Adsorption of impurities at *kinks* reduces the number of kinks available for growth. As growth proceeds through integration at kinks, the step velocity and

Fig. 3.17 The barrier presented by immobile impurities at the step motion on a ledge. The layer overcomes the impurities at a reduced rate if their distance is higher than the diameter of the critical nucleus

growth rate are decreased and eventually stopped. Examples and lists of experiments on kink adsorption are given in many papers [3.91, 149, 150, 156, 159–161]. Adsorption in kinks, by increasing x_0 , the mean distance between kinks, may cause polygonization of growth steps [3.160].

Impurities adsorbed at *steps* represent a steric barrier to diffusion of growth units along the step and to their entry into the kinks (Fig. 3.17). The step can move at a reduced rate only if the distance between two adsorbed impurities along the step is $s > 2r^*$; otherwise they are stopped.

Adsorption at steps is found to have occurred in many experiments [3.155, 156, 158, 160].

Besides the above kinds of adsorption, another possibility arises when the impurity concentration is high and strong lateral interactions occur among the molecules. A 2-D adsorption layer may form which has structural similarity with the growing face, as discussed in Sect. 3.2.3. The formation of the adsorption layer is easier with large molecules. The existence of an adsorbed solution layer, strongly structured at the interface, was suggested by Sipyagin and Chernov, who found that the layer may be disturbed by the addition of alcohol, which increases the growth rate [3.93].

3.8.4 Effect of Impurity Concentration and Supersaturation

The impurity effectiveness is very variable. To affect crystal habit, some g/l may be necessary (e.g., Na_2SO_4 for NaCl) or ppm are already sufficient (e.g., $\text{Na}_2\text{Fe}(\text{CN})_6$ for NaCl). A low or very low impurity concentration (C_i) may increase the growth rate due to its influence on the edge free energy, but higher C_i affecting the kinetic parameters may cause a sharp decrease. This effect is selective, as only some spe-

Fig. 3.18 (a) Ammonium sulfate crystals grown from pure solution and (b) in presence of 100 ppm Al^{3+} (after [3.163])

cific faces of a given crystal are concerned, and the crystal habit is modified. This occurs with organic and inorganic impurities (Fig. 3.18). For example, the growth rate of the {101} faces of **KDP** slowly increases, then decreases with increasing C_i of Fe^{3+} and Cr^{3+} , whereas it is not affected by Co^{2+} and Ni^{2+} [3.162]. Some ppm of Cr^{3+} are able to increase the step bunch spacing on the {100} faces of **ADP**, and some more to stop the formation of bunches [3.160].

Coupling of supersaturation and impurity concentration can have strong effects. Impurities are usually more efficient at low than at high supersaturation, where competition favors the adsorption kinetics of growth units with respect to that of impurities. For any impurity concentration there is a critical supersaturation σ^* below which growth is stopped (dead zone); the value of σ^* increases with C_i . A distinction is made between regular and irregular growth, according to whether an impurity changes the growth mechanism or

Fig. 3.19a–c Growth curves (R_{hkl} versus σ) for regular (a) and irregular (b,c) growth of different crystals in the presence of small and large impurity molecules, respectively, at increasing impurity concentrations. (a,b) (110) faces of $\text{C}_{36}\text{H}_{74}$ in the presence of an amine and a copolymer, respectively; (c) different faces of sodium perborate crystals. For a detailed description see [3.93, 150, 161]

Fig. 3.20 Morphodrome (β versus $\text{Li}^+/\text{Ca}^{2+}$) of calcite crystals grown in the presence of Li^+ as impurity (after [3.72])

not, as can be seen from the curves for R_{hkl} versus β (Fig. 3.19).

In regular growth, the curves for impure solutions run parallel to that of pure solution, suggesting an unchanged growth mechanism, whereas in irregular growth the growth rate is stopped at low supersaturation, but starts at higher σ values. In this case impurities adsorbed on crystal surface promote step bunching and originate an irregular crystal morphology [3.93]. Growth rate fluctuations were observed in both static and kinetic regimes [3.78]. Many examples of the effects of supersaturation and impurity concentration are reported in [3.158, 160, 161]. These effects may be represented through morphodromes (Figs. 3.14 and 3.20) (Sect. 3.2.3).

Effects of impurities on 2-D islands lying on the (001) surface of a Kossel crystal have been simulated and a morphodrome calculated in which, due to the roles of edge diffusion and kink poisoning, an initial square crystal changes to a diamond with increasing β and C_i , in qualitative agreement with experimental observations [3.164].

3.8.5 Effect of Impurity Size

Three kinds of impurities are usually distinguished: ions and small molecules, polyelectrolytes, and tailor-made additives, the molecular weights of which are on the order of about 10^2 , 10^3 , and 10^4 , respectively [3.147]. The former may be mobile or immobile, while the two

latter types are nearly immobile with great effect on crystal habit and incorporation in the surface layers. A fourth class could be added, the amphiphiles (dyes, surfactants).

Ions

In crystal growth from aqueous solutions ions are often present as impurities. Their interaction with the crystal surface depends on their charge and size and on the structural properties of the crystal faces. For example, the divalent (Co^{2+} , Ni^{2+} , Ba^{2+}) cations generate greater local strains and surface change than the trivalent (Fe^{3+} , Cr^{3+}) ones on the surface of KDP faces due to the incorporation of the former and adsorption of the latter on the surface layer [3.162]. Interactions of divalent (Cd^{2+} , Ni^{2+}) and trivalent (Al^{3+} , Cr^{3+} , Fe^{3+} , La^{3+} , Ce^{3+}) cations with some inorganic crystals (gypsum, KDP, potassium hydrogen phthalate (KAP), etc.) are reported in [3.147]. Ions can be selectively incorporated into the different faces, such as Cr^{3+} and Fe^{3+} more easily included into {100} than into {101} faces, and also into different slopes of a vicinal hillock [3.103]. It is difficult to predict the influence of ionic impurities. For example, a number of divalent cations and anions have no significant effect on the crystal habit of gibbsite, which conversely undergoes dramatic changes in the presence of alkali ions (K^+ , Cs^+) [3.165]. The Ba^{2+} and Pb^{2+} cations have opposite effects on the growth of the {111} and {100} faces of $\text{Sr}(\text{NO}_3)_2$ [3.166]. There is no general criteria to interpret the effect of ions on crystal habit, although a guideline may be the hypothesis of the formation of an ordered adsorption layer at the interface. When an ion is incorporated to form a solid solution, it distributes between the crystal (c) and the solution (s) according to a partition coefficient $K_{eq} = C_c/C_s$. The surface acts as a source or sink for the ion depending on whether K_{eq} is less than or greater than 1. The role of inclusions of isomorphous impurities during crystal growth is widely discussed in a review paper [3.167].

Polyelectrolytes

Polyelectrolytes, which include soluble polymers, proteins, and polysaccharides, are all characterized by an array of polar groups on an open long chain, by which they may be effective at a ppm level. Summarizing the interaction between polyelectrolytes and sparingly soluble salts, two principles were enunciated: the dimensional fit between the functional groups of the impurities and the interionic distance on the surface, and the achievement of stereochemical constraints [3.168].

Fig. 3.21a–d Crystals of $\text{Ni}(\text{NH}_4)\text{PO}_4 \cdot 6\text{H}_2\text{O}$ grown in the presence of increasing ammonia excess. The crystals are elongated along $[100]$ in **(d)** and along $[010]$ in **(a–c)**. Bars: $40\ \mu\text{m}$ (after [3.170])

Any macromolecule may function selectively as a retardant or promoter, depending on specific conditions. A lot of research has been carried out on the influence of polyelectrolytes and biopolymers on the crystallization of biominerals, such as calcium carbonate and other mineral compounds (gypsum, fluorite, barite) [3.147, 154] and calcium oxalates, components of lithiasis [3.169].

Tailor-Made Additives

A special case of impurities is represented by tailor-made additives, which are used in organic crystallization to change habit. Their main characteristic is the partial resemblance of their molecular structure to that of the crystal molecules (Sect. 3.2.3). A wide list of experiments on tailor-made additives is given in the monograph [3.14]. Normal-paraffins that are used as solvents for the growth of lower and higher homologous can be considered as tailor-made additives [3.93, 129].

Molecules with long and rigid chains are easily adsorbed at the interfaces, whereas molecules with too long chains tend to fold, forming a 2-D heterogeneous nucleus on the surface, which promotes crystal growth [3.48]. To simulate the morphological change due to additives, the built-in approach and the surface docking approach were applied. The former works only if the intermolecular bonding is anisotropic, whereas the latter can be applied to both isotropic and anisotropic bonding [3.171].

3.8.6 Composition of the Solution: pH

In an ionic impurity-free solution, change of habit may occur when there is an excess of either cation or anion or when pH is changed:

1. The former case is presented by calcite, which assumes an elongated habit in the presence of

an excess of Ca^{2+} and becomes tabular when CO_3^{2-} ions are in excess [3.172]. Many other cases are known; we quote silver bromide, which crystallizes as a cube from stoichiometric solution, but as an octahedron in excess bromide [3.173]. $\text{Ni}(\text{NH}_4)\text{PO}_4 \cdot 6\text{H}_2\text{O}$ crystals grown in excess ammonia change from a needle-like habit to a pseudocubic symmetry due to $\text{Ni}(\text{NH}_3)_x(\text{H}_2\text{O})_{6-x}$ complexes selectively adsorbed at the surfaces (Fig. 3.21) [3.170]. A detailed analysis of the chemical aspects of the impurity effects is given in the paper [3.174].

- The effect of pH on crystal shape has been studied for a long time, especially for **ADP** and **KDP** by Russian researchers [3.175]. The change in pH modifies the concentration ratios of the chemical species in solution, especially of polyprotic acids. The growth rates of the $\{101\}$ and $\{100\}$ faces of **ADP** are differently affected by pH with change in crystal elongation, attributed to the role played by either hydration of NH_4^+ , H_2PO_4^- or $\text{NH}_4\text{PO}_4^{2-}$ ions or the concentration of hydroxonium ions $[\text{H}_3\text{O}(\text{H}_2\text{O})_3]^+$

in solution [3.115]. Addition of Fe^{3+} and Cr^{3+} causes crystal tapering, which is a function of pH. Change in pH does not affect the growth rate of $\{101\}$ faces of **KDP**, but when pH differs from the value corresponding to solution stoichiometry, the $\{100\}$ faces increase in size and crystals become more isometric. This effect is related to the change with pH of surface parameters (step velocity and hillock slope) on the two faces [3.176]. A small pH decrease causes a dramatic increase in growth rate in the $[001]$ direction and a decrease in the $[010]$ direction on L(+)-glutamic acid hydrochloride due to the formation of dimers at low pH, which selectively interact with the two directions [3.177]. The role of pH in crystal growth is fundamental in the presence of amino acids. Glycine exists in aqueous solution as zwitterions ($\text{H}_3\text{N}^+\text{CH}_2\text{COO}^-$) in a definite range of pH, in which the critical supersaturation necessary to obtain the $\{110\}$ form of NaCl attains its minimum value. The effect is explained by admitting adsorption of zwitterions along the $[001]$ directions on the $\{110\}$ faces [3.65].

3.9 Other Factors

Crystal habit can be affected by (not less important) factors other than those mentioned above. Some of these are briefly considered below, while some (electric field, ultrasound, pressure, microgravity) are neglected.

3.9.1 Temperature

The influence of temperature on crystal growth is multifaceted. Not only does it directly promote growth, as results from the growth rate formulas, but it also affects

other factors that act on the growth rates: solubility, surface roughness, solvent/solute-interface interactions, and chemical equilibria. Since these factors work in a selective way on different faces, a change in temperature may cause relevant changes in crystal habit, as shown in experiments since the beginning of the 20th century. Some cases are quoted in [3.115, 126, 178]. Clear anomalies were detected in curves of R versus T for some salts (KCl, NaClO_3 , and KClO_3). Sipya-gin, Chernov, and Punin, quoted in [3.93], found that at definite temperatures the adsorbed layer at the crystal surface undergoes structural change, which suggests the occurrence of a third step between volume diffusion and surface diffusion. Significant changes were observed in sucrose crystals, in which the $\{101\}$ form dominates the other $\{h0l\}$ forms at 30°C , rendering crystals elongated, whereas at 40°C it becomes less important and crystals appear isometric. Growth sectors occur at any T and σ (Fig. 3.22) [3.46].

Fig. 3.22 Crystal habit of sucrose seen along $[010]$, grown at 30 and 40°C and at increasing σ values (after [3.46]) ◀

3.9.2 Magnetic Field

Research on the effects of a magnetic field on crystal growth started with the magnetic treatment of hard water in order to prevent scale formation. The number of papers on this topic is increasing due to its practical importance and criticism of results and reproducibility. A magnetic field has been recognized as affecting nucleation and crystal growth rate, polymorphism, and colloidal stability, and is now being applied to crystal growth of proteins and other compounds. In research on many poorly soluble inorganic salts a marked effect was only found for diamagnetic salts of weak acids (carbonates and phosphates): a magnetic field (0.27 T) increased their nucleation and growth rates. No effect on paramagnetic salts was recorded. These results are attributed to faster proton transfer from H-carbonate and H-phosphate ions to water molecules, due to proton spin inversion in the external field [3.179]. Also surface features are sensitive to the effects of magnetic field, as observed in the shape of etch pits and the shift of dislocations on paracetamol crystals [3.180]. Applying a strong magnetic field (10 T) to a lysozyme solution increases its viscosity and birefringence, which suggests molecular ordering with the formation of interconnected network, i. e., gel phase [3.181]. Experiments are also being carried out in gels, where magnetic field orientates PbBr_2 nanocrystallites and markedly increases their size [3.182]. Notwithstanding the amount of research in this area, the observed effects are as yet not adequately explained and no definite theory has been presented; indeed this is a new field of research.

3.9.3 Hydrodynamics

Crystal growth can take place under static or dynamic conditions. In the former case, which occurs in solution at rest and in gels, volume diffusion plays a decisive role in the growth kinetics. The latter condition is realized by stirring or shear flow. In this case the growth rate progressively increases with stirring or flow rate up to a limiting value which depends on the supersaturation. Beyond this value, the volume diffusion process does not influence the growth rate and surface diffusion becomes dominant [3.183]. The effects on crystal habit are different. Under static conditions concentration gradients are set up in solution and at the crystal surface, where they promote 2-D nucleation and the formation of hollow crystals and dendrites, depending on the supersaturation. Even in a solution at rest or zero gravity the crystal growth itself engenders convection, which influences morphological stability [3.184]. In a suitable stirred solution there are no concentration gradients except in the boundary layer, which is admittedly covering the crystal surface, and all the crystal faces are in contact with a homogeneous solution. Indeed, supersaturation is not constant along the face even in the kinetic regime [3.78], which may cause inclusions during growth. When a shear flow is applied, there are effects on crystal habit and surface features. The face on which flow is direct grows faster than the opposite face which is fed by a less supersaturated solution. In addition, a shear flow in the direction of step motion favors instability, whereas flow in the opposite direction enhances stability [3.87, 89].

3.10 Evolution of Crystal Habit

When a crystal with a given growth shape is left in contact with its mother solution, reaching saturation, rearrangements occur at the crystal–solution interface in order to achieve the minimum surface energy. A classical example is represented by NH_4Cl dendrites, which when grown in a small drop transform into a single crystal that corresponds to the equilibrium form (Fig. 3.6). Crystal habit evolution can also be observed in the growth from supersaturated solutions of poorly soluble compounds. In Fig. 3.23 the change with time of growth forms of $\text{MgHPO}_4 \cdot 3\text{H}_2\text{O}$, precipitated from solutions

of different concentration, is shown. There is a progressive decrease of supersaturation, which goes together with the habit change, which continues even when the solution has become saturated. The general trend, independent of the initial concentrations, is towards the same crystal shape [3.185].

Another kind of evolution takes place when a crystal, grown in a given solvent, is transferred to a supersaturated solution of another solvent. The original faces are slowly replaced by others that are stable in the new solution, as observed for mercuric iodide crystals

Fig. 3.23 Change of pH and crystal habit versus time of $\text{MgHPO}_4 \cdot 3\text{H}_2\text{O}$ crystals precipitated from equimolar solutions of different initial concentration. Dominant final forms: $o\{111\}$; $b\{010\}$ (after [3.184]) ◀

grown in aqueous solutions and subsequently inserted into methanol solutions [3.142]. A more drastic change occurs when several crystal phases may form from a supersaturated solution, as in the case of Ca-phosphate solutions. The normally stable phase is hydroxyapatite, which is the less soluble phosphate, but, obeying Ostwald's step rule, other more soluble phases nucleate first, even an amorphous phosphate at high pH. These phases are not stable, since the solution is still supersaturated with respect to the less soluble ones. A long process of chemical reactions starts in solution, which involves the nucleation of the more stable crystal phase and the dissolution of the first one [3.186].

3.11 A Short Conclusion

At the end of this concise review it is apparent that the crystal morphology is the result of the complex interaction of several factors – structural, thermodynamic and kinetic –, which make difficult and yet fascinating the study of this field. The great variability of the shape and size of crystals grown from solutions is mainly due to the capability of the crystalline structure of a compound to show different interfaces as a response to the variations introduced by the environment (solvent, impurity,...). The interaction of these inter-

faces with kinetic factors (such as supersaturation) give rise to the different morphologies and habits for the same crystal phase. On the contrary the shape, size and development of the living organisms are controlled by a genetic program which gives the same pattern to all individuals of a given species. An interesting field of combined research is bio-mineralization, where to the interplay of crystal structure and environment it is necessary to add the biological activity of the living organisms.

3.A Appendix

3.A.1 The Equilibrium Pressure of an Infinite Monoatomic Crystal with Its Own Vapor

From statistical thermodynamics the chemical potential of a molecule in a perfect gas reads

$$\mu^g = \varepsilon_p^g - k_B T \ln \Omega_g + \mu^0. \quad (3.A1)$$

The first term, ε_p^g , is the potential energy of the gas molecule, while the two last terms represent the entropy of dilution and the thermal entropy, respectively. Ω_g is the mean volume occupied in the gas phase, and $\mu^0 = k_B T \ln[h^3(2\pi mk_B T)^{3/2}]$ depends only on the mass of the molecule and on T . In a perfect monoatomic and infinite Einstein crystal (fulfilling the condition

$T \gg (h/k_B)\nu_E$, where ν_E represents the unique vibration frequency) the chemical potential of one atom occupying a mean volume Ω_c is

$$\mu_{c\infty} = \varepsilon_p^{c\infty} - k_B T \ln \Omega_c + \mu^0, \quad (3.A2)$$

where $\varepsilon_p^{c\infty}$ is the potential energy of the atom in any lattice site. At crystal–vapor equilibrium the chemical potentials of the two phases are the same, which implies

$$\varepsilon_p^g - \varepsilon_p^{c\infty} = k_B T \ln \left(\frac{\Omega_g}{\Omega_c} \right).$$

At equilibrium,

$$\Omega_g = k_B T / p_{\infty}^{\text{eq}} \quad \text{while} \quad \Omega_c = (k_B T / 2\pi m)^{3/2} \nu_E^{-3}.$$

Being necessarily $\varepsilon_p^g > \varepsilon_p^{c\infty}$, we can define the extraction work of an atom from a mean lattice site (kink) to

the vapor $\varphi_{c\infty} = \varepsilon_p^g - \varepsilon_p^c \infty > 0$ and then, from the preceding relation, one obtains the equilibrium pressure of a perfect monoatomic and infinite Einstein crystal

$$p_{\infty}^{\text{eq}} = \left[(2\pi m)^{\frac{3}{2}} (k_B T)^{-\frac{1}{2}} v_E^3 \right] \exp(-\varphi_{c\infty}/k_B T). \quad (3.A3)$$

4. Generation and Propagation of Defects During Crystal Growth

Helmut Klapper

This chapter presents a review of the typical growth defects of crystals fully grown on (planar) habit faces, i. e., of crystals grown in all kinds of solutions, in supercooled melt (mainly low-melting organics) and in the vapor phase. To a smaller extent growth on rounded faces from the melt is also considered when this seems appropriate to bring out analogies or discuss results in a more general context. The origins and typical configurations of defects developing *during* growth and *after* growth are illustrated by a series of selected x-ray diffraction topographs (Lang technique) and, in a few cases, by optical photographs.

After an overview (Sect. 4.1) the review starts with the formation of inclusions (Sect. 4.2), which are the main origin of other growth defects such as dislocations and twins. Three kinds of inclusions are treated: foreign particles, liquid inclusions (of nutrient solution), and solute precipitates. Particular attention is directed to the regeneration of seed crystals into a fully faceted shape (*capping*), and inclusion formation due to improper hydrodynamics in the solution, especially for potassium dihydrogen phosphate (KDP).

Section 4.3 deals briefly with striations (treated in more detail in Chap. 6 of this Handbook) and more comprehensively with the different kinds of crystal regions grown on different growth faces: growth sectors, vicinal sectors, and facet sectors. These regions are usually differently perfect and possess more or less different physical properties, and the boundaries between them are frequently faulted internal surfaces of the crystal. Two subsections treat the optical anomalies of growth and vicinal sectors and the determination of the relative growth rates of neighboring growth faces from the orientation of their common sector boundary.

In Sect. 4.4 distinction is made between dislocations connected to and propagating with the growth interface (*growth dislocations*), and

dislocations generated *behind* the growth front by plastic glide due to stress relaxation. The main sources of both types of dislocations are inclusions. In crystals grown on planar faces, growth dislocations are usually straight-lined and follow (frequently noncrystallographic) preferred directions depending on the Burgers vector, the growth direction, and the elastic constants of the crystal. These directions are explained by a minimum of the dislocation line energy per growth length, or equivalently by zero force exerted by the growth surface on the dislocation. Calculations based on anisotropic linear elasticity of a continuum confirm this approach. The influence of the discrete lattice structure and core energy on dislocation directions is discussed. Further subsections deal with Burgers vector determination by preferred directions, postgrowth movement of grown-in dislocations, generation of postgrowth dislocations, and the growth-promoting effect of edge dislocations.

Section 4.5 presents *twinning*, the main characteristics of twins and their boundaries, their generation by nucleation and by inclusions, their propagation with the growth front, and their growth-promoting effect. Postgrowth formation of twins by phase transitions and ferroelastic (mechanical) switching is briefly outlined. Finally, Sect. 4.6 compares the perfection of crystals (KDP and ammonium dihydrogen phosphate (ADP)) slowly and rapidly grown from solutions. It shows that the optical and structural quality of rapidly grown crystals is not inferior to that of slowly grown crystals, if particular precautions and growth conditions are met.

4.1 Overview

The present chapter mainly deals with growth defects in crystals fully grown on (planar) habit faces. To a smaller extent crystals grown on rounded faces from the melt are also considered when this seems to be appropriate to bring out analogies or discuss results in a more general context. Crystals grow on habit faces in solutions, supercooled melts, and vapor. A special feature of this growth method is that there is practically no temperature gradient inside the crystal, provided that facet growth occurs freely on the whole surface of the crystal (without contact with a container wall). This is also the case for growth in the supercooled melt: the crystallization heat released at the growing habit faces keeps these at the crystallization temperature – or at least close to it [4.1]. The absence of a temperature gradient, and thus of thermal stress, inside the crystal allows the development of defect structures according to first thermodynamical principles and their preservation in their as-grown geometries, unless thermal gradients are introduced by improper cooling to room temperature after growth. This particularly concerns dislocations in crystals growing in their plastic state. Dislocations are the essential elements of stress relaxation by plastic glide: they are generated, moved, and multiplied by stress. Thus – in the presence of thermal stress – it makes an essential difference whether crystals are grown in their brittle or their plastic state. From solution, crystals grow in the brittle or in the plastic state (depending on the specific mechanical properties at the growth temperature); from the melt, however, crystals *always* grow in the

plastic state, because each material has a more or less extended plastic zone below its melting point. It will be shown that growth dislocations develop the same geometrical features in crystals grown on habit faces from solution in the brittle state and from supercooled melts in the plastic state, provided that thermal gradients are absent.

In this review the generation of defects at the interface and their propagation with the advancing growth front are considered separately. This is because certain defects formed by a growth disturbance (e.g., by inclusions) may *heal out* and do not continue into the further growing crystal, whereas other defects (dislocations, twins, and grain boundaries), once initiated, are *forced* to proceed with the interface despite growth under optimal conditions. These defects can only be eliminated by growing out at the sides of the crystal, e.g., during Czochralski pulling on interfaces which are convex toward the melt. Moreover, distinction is made between *defects always connected to the interface (growth defects, especially growth dislocations)* and *defects generated “behind” the growth front (postgrowth defects)*. The latter defects may be formed already during the growth run, either by thermal stress or by precipitation. Furthermore, defect configurations may be preserved in their *as-grown* geometry or changed after growth (e.g., by *postgrowth* movement of dislocations).

Many experimental results and the majority of photographs presented in this review were obtained by growth experiments and x-ray topographic studies

(Lang technique) in the author's laboratories in Aachen and Bonn. Crystals were grown from aqueous and organic solutions, from supercooled melts (organics), and by Czochralski pulling (organics). The organic crystals were considered as low-melting *model substances* (melting points below 100 °C), chosen with the primary aim of studying the generation and propagation of growth defects in dependence on growth methods

and varying growth conditions. The main characterization method, x-ray diffraction topography, is not treated here; the reader is referred to the reviews [4.2–5] in the literature and to Chap. 42 in this Handbook. More specialized x-ray topographic treatments are given for twinned crystals [4.6] and for organic crystals [4.7]. Earlier reviews on the generation and propagation of growth defects were published by the author [4.8–11].

4.2 Inclusions

Two categories of inclusions are distinguished according to their origin [4.12, 13]: *primary inclusions* are associated with the growth front, i. e., they arise during growth, whereas *secondary inclusions* are formed after growth. Primary inclusions are *key defects* because they are the source of other defects (dislocations, twins) which propagate with the growth front into the further growing crystal. Inclusions of both categories may form stress centers which give rise to dislocation loops or half-loops by plastic glide (stress relaxation). Among the primary inclusions, three kinds are distinguished:

- Foreign particles
- Solvent (liquid) inclusions in crystals grown from solutions
- Solute precipitations in crystals grown from impure or doped melts.

Secondary inclusions are precipitates of solute impurities (dopants) formed after growth in the solid state during slow cooling, annealing or processing of crystals which are grown at high temperatures. They are due to the supersaturation of solutes at temperatures below the temperature at which the crystal was grown. These solutes precipitate if their diffusion mobility is sufficiently high and not frozen-in (as is usually the case at room temperature). In the same way vacancies and self-interstitials may condense into dislocation loops and stacking faults, e.g., during processing silicon crystals for electronic applications (*swirl defects*, e.g., [4.14]).

Here we treat only primary inclusions. A very detailed theoretical and experimental treatment of the capture of inclusions during crystal growth is presented by Chernov and Temkin [4.15]. A similar study with particular consideration of crystallization pressure is reported by Khaimov-Mal'kov [4.16].

4.2.1 Foreign Particles

Foreign particles preexisting in the nutrient (solution, melt) increase the risk of (heterogeneous) nucleation. Their incorporation into the growing crystal, however, is often considered as not very critical due to the crystallization pressure [4.16] (*disjoining force* after Chernov and Temkin [4.15]) which repulses foreign particles from the growth interface. Nevertheless, particles coming into contact with the growth face may be incorporated, depending on the size and chemical/physical nature of the particles and on growth conditions such as stirring, growth rate, and supersaturation [4.15]. For example, potassium alum crystals can be grown inclusion free (as assessed by optical inspection and x-ray topography) from *old* (i. e., repeatedly used) unfiltered aqueous solutions containing many floating dust particles, provided that growth conditions (temperature control, stirring) are stable enough to avoid the formation of liquid inclusions (see below). On the other hand in crystals of benzil grown in *old* (repeatedly filled up) supercooled melts ($T_m = 96\text{ °C}$), flocks of solid decomposition products floating in the melt are quite readily incorporated (unpublished observation by the author). In contrast to the solution growth of potassium alum, such benzil melts were not stirred, but thermal convection occurred due to the release of crystallization heat at the crystal surface [4.1]. In the latter case the incorporation seems to be favored by the higher viscosity and the lower agitation of the nutrient phase, and probably also by the chemical similarity (carbon) of the particles to the growing crystal.

Foreign solid inclusions are very common in minerals. In laboratory and industrial crystal growth they usually play a minor role because they are easily avoided by filtering of the nutrient before growth. If solid inclusions appear during the growth run, e.g.,

as abrasives of the stirring device, continuous filtering is advised. This has been demonstrated by Zaitseva et al. [4.17] for the rapid growth of huge potassium dihydrogen phosphate (KDP) and deuterated potassium dihydrogen phosphate (DKDP) crystals with linear sizes up to 55 cm: continuous filtering during the whole growth run considerably increased the optical quality and laser damage threshold of these crystals.

The intentional incorporation of particle inclusions for the study of the generation of dislocations is reported in Sect. 4.4.2. The intentional inclusion of oil drops during crystallization from solutions was studied by Kliia and Sokolova [4.18].

4.2.2 Solvent Inclusions

Solvent inclusions are very common in crystals grown by all variants of solution growth (aqueous and organic solvents, flux). Two origins are distinguished.

Faceting (Capping) of Rounded Surfaces

In general crystals grow from solutions with planar faces (habit faces), whereby faces with low surface energy grow slowly and determine the final morphology of the crystal (*Wulff theorem* [4.19]). If surfaces are rounded, (e.g., of the seed crystal or after redissolution), during first growth, facets of habit faces and (between them) terraces of these faces are formed. The facets become larger and the terraced regions grow out until a single edge between the two habit faces engaged is formed, as shown in Fig. 4.1 (*theorem of Herring* [4.20–23]; see also *growth on spheres* [4.24] and [4.25, p.130]). The *healed-out* regions often have the shape of caps (*capping region*). The growth on terraced surfaces favors the entrapment of solvent inclusions, which may lead in extreme cases to a spongy structure of the capping region. This usually happens during first growth on seed crystals which were rounded

Fig. 4.1 Faceting and *capping* on rounded crystal surfaces. The shaded regions of terraced growth favor entrapment of liquid inclusions. They grow out and finally form the growth-sector boundary between the main habit faces

Fig. 4.2 A KDP crystal (length 45 mm) with {011} capping pyramid on a {001} seed plate

during a final etching (which is necessary in order to remove surface impurities and defects) before seeding-in. Therefore the zone of first growth around the seed crystals is usually more or less disturbed by liquid inclusions. These inclusions, however, can be largely avoided by a very slow (and thus time-consuming) growth under low supersaturation during the seed-faceting period.

A conspicuous example of capping is provided by potassium dihydrogen phosphate (KDP) grown in aqueous solution on {001} seed plates (Fig. 4.2). KDP develops habit faces {100} (tetragonal prism) and {011} (tetragonal dipyrmaid), but {001} is not a habit face. Thus in the first stage of growth on a {001} seed plate a spongy capping zone in the form of a tetragonal pyramid {011} over the seed plate as basis is formed, followed by clear further growth on {011} pyramid faces (Fig. 4.2). Detailed descriptions of this {001} capping process in KDP and ammonium dihydrogen phosphate (ADP) crystal growth are presented by Zerkoss and Slawson [4.12] and Janssen-van Rosmalen et al. [4.26].

Fluctuation of Growth Conditions (Growth Accidents)

A sufficiently strong change of growth condition (e.g., of supersaturation, stirring rate, stirring direction) may introduce – due to local variations of supersaturation – a (temporary) instability of growth faces: regions of retarded and promoted growth occur, leading to elevations

and depressions on the growth face. Overhanging layers then spread over the depressions and close them, thus trapping nutrient solution. Usually a group of inclusions arranged in a plane parallel to the growth face is formed (*zonal inclusions*, Fig. 4.3). If all growth faces of the crystal are affected by the same growth disturbance, inclusions are formed on all faces. After stabilization of growth conditions and further clear growth the inclusions, which are visible by scattered light (if the crystal is transparent), reveal the shape of the crystal at the instant of the disturbance (*phantom crystal* in mineralogy). This is often observed when, after an accidental (or intentional) temporary redissolution, the crystal is rounded, so that during further growth refaceting with increased tendency for inclusion trapping occurs. Due to the capping effect, these inclusions are concentrated and most visible in the edge regions of the crystal [4.27] (Fig. 4.1).

The tendency to form solvent inclusions may strongly depend on the type of growth face $\{hkl\}$. In general the formation of solvent inclusions is fa-

Fig. 4.3 Liquid (*zonal*) inclusions in solution-grown potassium alum (water), triggered on a $\{110\}$ face by intentionally introduced redissolution due to a temporary increase of the solution by 1°C . The original temperature (about 40°C) was restored after a slight rounding of the crystal edges had appeared. Arrow *n*: growth direction. A few edge dislocations originate from the inclusions. Section ($6 \times 12\text{ mm}^2$) of an x-ray topograph of a 0.9 mm -thick $\{001\}$ plate. Diffraction vector $\mathbf{g}(2\bar{2}0)$, MoK_α radiation

vored on faces with high surface (attachment) energy, and thus high growth rate. An instructive example is provided by potassium alum growing from aqueous solution: fluctuations of growth conditions lead to pronounced liquid-inclusion entrapment on the smaller and fast-growing cube faces $\{100\}$, whereas the slow and morphologically dominant octahedron faces $\{111\}$ resist the formation of inclusions even for strong changes of growth parameters [4.27]. There are also crystals for which certain growth faces trap tiny liquid inclusions despite controlled growth conditions. An example is shown in Fig. 4.4: The two pinacoid growth sectors of the crystal appear milky due to light scattering at solvent inclusions, whereas sectors of other faces are optically clear. The reason for the preferred inclusions trapping on certain growth faces is their specific surface structure, which favors the incorporation of solvent molecules and the formation of solvent bubbles. This phenomenon is known as *hourglass inclusions*, of which two types are distinguished: (1) face-specific preferential formation of liquid bubbles (which is the case in Fig. 4.4), and (2) preferential absorption of solvent and other foreign molecules as solid solution in the host crystal (without the formation of bubbles or solid precipitates). A well-known and frequently studied example of *hourglass inclusions* of type 2 is provided by potassium sulfate (e.g., Buckley [4.25, p. 415–420], Vetter et al. [4.28]; see also *dyeing crystals* [4.29, 30]). It is also repeatedly referred to in Sect. 4.3 of this chap-

Fig. 4.4 Preferred liquid-inclusion entrapment in the $\{201\}$ pinacoid growth sectors of monoclinic Tutton salt $\text{K}_2\text{Zn}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$ grown from aqueous solution under well-controlled conditions (horizontal diameter 35 mm). The crystal plate, cut from a bulk crystal, contains the seed crystal with the nylon thread for suspension in the solution

ter. Often the preferred formation of liquid inclusions on certain growth faces can be largely suppressed by a proper pH value.

The hydrodynamics of the solution flow around the growing crystal may also play a significant role in the formation of liquid inclusions (e.g., Chernov et al. [4.31]). A particularly interesting example of this influence for the growth of KDP crystals is reported by Janssen-Van Rosmalen and Bennema [4.32], Janssen-van Rosmalen et al. [4.26], and van Enckevort

et al. [4.33]. In their experiments the KDP crystals (shape: tetragonal prism $\{100\}$ terminated on both side by dipyrmaid $\{011\}$) were mounted on a *tree* which rotated in the solution. The solution was flowing toward one (front) and away from the other (rear) pyramid. On pyramid faces on the trailing side, solvent inclusions are often formed in a quasiperiodic sequence (Fig. 4.5), whereas on the front side inclusions do not appear. This phenomenon is explained by the hydrodynamic situation at the rear-side pyramid face: in the wake *behind* the crystal a swirling region with no or strongly reduced liquid exchange with the bulk mother solution is formed. Thus the saturation decreases locally and growth is retarded compared with regions neighboring edges of the growth face. This leads to a depression in the growth face. After some distance of further growth this cavity is overgrown, forming a solvent inclusion. As shown in Fig. 4.5, this process is repeated several times in a quasiperiodic manner. A detailed study of this effect, including flow simulation experiments in a model system, is presented by Janssen-Van Rosmalen et al. [4.26], Janssen-Van Rosmalen and Bennema [4.32], and van Enckevort et al. [4.33], who also report that the formation of these inclusions is avoided by stronger stirring, in their experiment by faster rotation of the crystal tree. In any case, strong stirring smoothes out supersaturation differences on the growth face and thus may largely avoid interface instabilities. This is particularly significant in the solution growth of very large crystals where high saturation differences between the edge regions and the center of a growth face may occur. For the *rapid growth* of KDP (e.g., [4.34–36]) and other crystals very strong stirring is a prerequisite for inclusion-free growth.

Finally a special type of liquid inclusions, so-called *hair inclusions*, is mentioned. These were, for example, observed by Smolsky et al. [4.37] in rapidly grown KDP; they consist of long hair-thin channels or strings of tiny bubbles filled with mother liquor. These pipes and strings are not arranged along the instantaneous growth front but form a more or less large angle with it, which indicates that they have proceeded with the growth front. Their origin is unclear for the most part, but in the case of KDP [4.37] it was shown by in situ atomic force microscopy of the growth face that at least some of them are triggered by tiny solid inclusions. As was shown by x-ray diffraction topography [4.37], these *hairs* are not correlated with dislocations. Thus they are different from the so-called *micropipes* (channels), frequently observed along the hexagonal axis of

Fig. 4.5 X-ray diffraction topograph of a (100) -plate (about 1.5 mm thick, about 50 mm high), cut from the rear side of a KDP crystal moved by rotation through the solution. Due to a closed wake of solution with reduced supersaturation behind the $(0\bar{1}1)$ growth face, liquid inclusions were repeatedly formed. They are the origin of numerous dislocations which grow out of the crystal at the side because the $\{010\}$ prism faces practically do not grow. The dislocations in the triangular region above the capping zone belong to one of the growth sectors (101) or $(\bar{1}01)$. They are inclined and emerge out of the plate at their top ends. Diffraction vector $g(020)$, $\text{AgK}\alpha$ radiation

beryl [4.38] and silicon carbide [4.39–41]. These channels are the hollow cores of screw dislocations with large Burgers vectors.

Liquid inclusions play a significant role in mineralogy because they allow the reconstruction of the conditions of mineral formation. A comprehensive review is given by Roedder [4.43].

4.2.3 Solute Precipitates

A critical parameter in the growth of crystals from melts containing solute impurities or dopants is the effective distribution (segregation) coefficient k_{eff} of the impurity (dopant) between melt and crystal (see Chap. 6 in this Handbook). If $k_{\text{eff}} < 1$ (which is mostly the case), the solutes are rejected by the growing crystal, which leads to a higher solute concentration in the melt in front of the growth interface. The excess solute diffuses away from the interface. For high growth rates, however, the solute concentration may become supersaturated, leading to the precipitation of the solute and incorporation into the crystal during further growth. Thus the solute precipitation is an interplay between k_{eff} , the characteristic time scale of solute diffusion in the melt, and the growth rate.

If a solute precipitation is triggered by a short temporary increase of the growth rate, a solitary sheet of precipitations, marking the instantaneous growth front, will be formed. If, however, the high growth rate is permanent, the precipitations extend in the growth direction and form so-called *solute trails* (e.g., [4.44]). In more extreme development they lead to constitutional supercooling with cellular and dendritic growth (see Chap. 6 in this Handbook).

As examples the formation of solute inclusions during melt growth of organic crystals is shown in Figs. 4.6 and 4.7. The melts of organic materials contain considerable amounts of solute atmospheric gas which is precipitated as small bubbles. Figure 4.6 shows bubble precipitation in Czochralski crystals of benzophenone [$(\text{C}_6\text{H}_5)_2\text{CO}$, $T_m = 48^\circ\text{C}$] induced by intentionally introduced changes of the growth conditions [4.42]. In the example of Fig. 4.6a, the pulling rate was temporarily increased from 0.4 to 0.6 mm/h, the other parameters remaining constant. This instantaneously led to bubble precipitation and reduction of the crystal diameter. The shape of the growth front at the instant of the intervention and its changes during further growth are clearly visible in dark-field light illumination. Note that the bubbles are also arranged in strings normal to the growth interfaces, corresponding to solute trails. After

about 2 h the pulling rate was again reduced to its former value of 0.4 mm/h. Then the crystal adopted its former width and the bubble precipitation stopped. Figure 4.6b shows the effect of an intentionally introduced transition from Czochralski growth to supercooled-melt growth by lowering the temperature of the melt from about 1.5°C above to about 1°C below $T_m = 48^\circ\text{C}$ and stopping the pull (but retaining the crystal rotation). The bubble precipitations reveal the transition of the concave (towards the melt) interface to a convex one. After the growth rate fell below the critical value, the bubble precipitation stopped. The crystal grew into the now supercooled melt and adopted a fully faceted shape at its end [4.42]. We have also observed that the (internal) surface of gas bubbles, precipitated in old and impure melts, were often covered with a layer of brownish material. This indicates that nongaseous impurities of the melt have been precipitated together with the solute gas.

Fig. 4.6a,b Bubble precipitation in Czochralski benzophenone ($T_m = 48^\circ\text{C}$) by an intentionally introduced change of growth parameters. Optical dark-field photographs of about 1.6 mm-thick plates. **(a)** Temporary increase of the pulling rate from 0.4 to 0.6 mm/h without change of other growth parameters. The diameter of the crystal is temporarily reduced from about 11 to 10 mm. **(b)** Transition from Czochralski growth to growth from supercooled melt by lowering the temperature from about 1.5°C above to about 1°C below T_m and stopping the pulling while retaining the rotation. The crystal grew into the now supercooled melt and became fully faceted. The arrows indicate the level of the melt after stopping the pulling (after [4.42])

Fig. 4.7a,b Bubble channels filled with gas in a prism growth sector of trigonal benzil ($T_m = 96^\circ\text{C}$) grown from supercooled melt ($5.6 \times 5.1 \text{ mm}^2$ section of a 2.2 mm-thick (0001) plate cut from the bulk crystal). Growth direction vertically downward. **(a)** Optical photograph. The channels originate from four gas bubbles sticking to the seed surface when starting growth. They have partially been filled by recrystallization within about 6 months after growth (see text). **(b)** X-ray topograph taken before the channels were closed. Note the glide-dislocation half-loops emitted from the channels (after [4.1]). Diffraction vector $\mathbf{g}(2\bar{2}00)$, $\text{CuK}\alpha_1$ radiation

Another instructive example is provided by Fig. 4.7, which shows a section of a benzil crystal ($(\text{C}_6\text{H}_5\text{CO})_2$, $T_m = 96^\circ\text{C}$) grown from slightly supercooled melt (ΔT about 1°C) with four gas inclusions elongated normal to the planar growth face (i. e., in the growth direction) [4.1]. The inclusions started from small bubbles sticking to the bottom side of the seed crystal already

during the seeding-in procedure. During further growth the growth rate was always below the critical rate for gas precipitation. Nevertheless, the bubbles advanced with the growth front and elongated and became even wider by collecting gas from the gas-rich zone in front of the growth face, thus leaving behind a gas-filled channel.

The photograph in Fig. 4.7a was taken about half a year after growth [4.1]. During this period the channels were partially filled by recrystallization, as can be recognized by the funnels in the surface at the bottom, indicating the former channel openings. Optically the recrystallized regions appear homogeneous except for a string of tiny scatterers (bubbles) aligned along the central axis of the former channel, revealed by optical dark-field observation. The mechanism of this recrystallization is not clear, but it probably occurred via sublimation, since the vapor pressure of benzil is relatively high, and the crystal was welded between two gastight plastic foils and, thus, stored in his own vapor.

Figure 4.7b shows an x-ray diffraction topograph taken shortly after growth was finished, when the channels were still open [4.1]. Numerous glide dislocations in the shape of half-loops emitted from the channel surface have formed (cf. also Sect. 4.4.6).

The entrapment of gas bubbles and their elongation into channels has been studied in detail by *Chernov* and *Temkin* [4.15], *Khaimov-Mal'kov* [4.16], and *Gegusin* and *Dziyuba* [4.45].

The relatively high concentration of solute gas in organic melts significantly limits the growth rate allowing bubble-free growth. Comparative growth experiments in outgassed supercooled melts under their own vapor showed that the growth rate for visually perfect growth could be increased by a factor of about three [4.46] compared with growth in gas-rich melts. In these experiments the growth rate (i. e., the supercooling), however, cannot be increased too much, because strong thermal upward convection in the melt (induced by the high release rate of heat of crystallization at crystal surfaces) leads to turbulent melt flow and serious defects (ragged growth) at the top end of the crystals.

Precipitation of solutes is a serious problem in melt growth of doped and mixed crystals. A detailed treatment is given in Chap. 6 in this Handbook. An instructive investigation of this effect, including an x-ray topographic study of dislocations formed around the precipitations, is reported by *Bardsley* et al. [4.44].

4.3 Striations and Growth Sectors

4.3.1 Striations

Striations are local variations of the impurity (dopant) concentration or of the crystal stoichiometry. They arise from fluctuations of growth conditions, such as changes of temperature, cooling rate, pressure, or convection in the solution or melt. These fluctuations lead to temporary changes in the growth rate, and thus to changes of the impurity incorporation. As a rule, they affect the whole growth front and thus form inhomogeneous layers parallel to the interface. The term *striations* is usually applied when the impurity layers appear in a (quasi)periodic sequence (Fig. 4.8a). If there are isolated layers, due to sporadic changes of growth conditions, often the term *growth bands* is used. In mineralogy, the term *growth zoning* is common. In crystals

grown under rotation, strictly periodic *rotational striations*, correlated with the rotation rate, may occur. They are due to a nonuniform radial temperature distribution around the rotation axis, leading to slight changes of growth conditions (even with remelting) within a rotation period.

The impurities may be contaminants of the solution or of the melt, or incorporated solvent components. Striations are also formed by dopants intentionally introduced with the aim of tailoring specific physical properties of the crystals. The rate of incorporation depends on the impurity (dopant) species and is governed by their distribution (segregation) coefficient with regard to the crystal to be grown.

The regions of different impurities/dopants form layers coinciding with the instantaneous growth front. In crystals grown on habit faces (from solution or supercooled melt) they are planar, as shown in Figs. 4.8a and 4.9. The *intensity* of the striations, i. e., the concentration of impurities, may be considerably different in distinct growth sectors (Sect. 4.3.2). This is due to different surface structures of different growth faces which may facilitate or impede impurity capture. Symmetrically equivalent growth sectors show the same *intensity* of striations unless the growth conditions (e.g., solution

Fig. 4.8 (a) Growth striations and growth-sector boundary in a crystal grown on planar (habit) faces. The sector boundary is an internal surface formed by the movement of the edge joining the two faces during growth. It separates regions of different growth directions. (b) Division of a fully faceted crystal into growth sectors. The vectors n_i indicate the growth directions. *Dashed lines*: contours of the crystal at different stages of growth. One of the growth sectors has *grown out*

Fig. 4.9 X-ray topograph of a (0001) plate (about 8 mm diameter, 0.35 mm thick) cut out of a quartz-homeotypic gallium phosphate GaPO_4 crystal grown from high-temperature solution in phosphoric/sulfuric acid (after [4.47]), showing the triangular arrangement of growth sectors with pronounced striations. Growth-sector boundaries are visible by topographic contrast or by bends of the striations. Diffraction vector $g(10\bar{1}0)$, AgK_α radiation

flow) at the corresponding growth faces are different. Conspicuous examples are the so-called hourglass growth patterns of crystals stained with organic dyes. *Staining of crystals* has been thoroughly studied by Kahr and Guerny [4.29] and Kahr and Vasquez [4.30]. Striations are often modified by growth hillocks (*vicinal pyramids*) as discussed in Sect. 4.3.3. An x-ray topographic study of the striation formation in the presence of vicinal pyramids in rapidly grown KDP crystals is presented by Smolsky et al. [4.48].

Crystals grown on rounded interfaces exhibit curved striations. An example of striations accompanied by tiny gas bubbles in a Czochralski crystal is shown in Fig. 4.10. Facets formed on rounded interfaces lead to regions (*facet sectors*, Sect. 4.3.4) with planar striations. The occurrence and *intensity* of these striations may be quite different from those of striations formed along

curved interfaces. This is due to distinct growth modes with different distribution coefficients for rough growth on curved interfaces and growth on facets from supercooled melt (cf. Chap. 6 of this Handbook).

In general, growth striations lead to local changes of physical properties (e.g., electric conductivity, optical birefringence). This is a major problem in the growth of doped crystals for sophisticated electronic and optical solid-state devices. This can be encountered by suppression of melt convection, e.g., by growth under microgravity [4.49] or by growth in magnetic fields [4.50, 51], which are treated in Chaps. 7 and 17 of this Handbook. An extensive treatment of the origin of striations and of recipes to largely avoid them is presented by Scheel [4.52].

4.3.2 Growth Sectors

Bulk crystals grow in all directions of space. Due to their structural and physical anisotropy, the types, distribution, and geometry of growth defects are distinct for different growth directions. This is pronounced in crystals grown from solutions and supercooled melts, which develop planar growth (*habit*) faces, and thus consist of regions (*growth sectors*) grown in discrete directions defined by the normals of the growth faces involved (Fig. 4.8b). Among all habit faces that are possible in principle, the *final* crystal usually exhibits only those faces which possess low surface (attachment) energies and thus – according to Wulff's theorem [4.19–21] – have low growth velocities. *Fast* faces with higher attachment energy grow out and vanish from the external morphology (cf. *Wulff–Herring construction* [4.20–23]). Thus the crystal may contain more growth sectors, usually in close neighborhood of the seed crystal, than are recognized from its final outward morphology (Fig. 4.8b).

Growth sectors are separated by growth-sector boundaries. These boundaries are internal surfaces over which the edges between neighboring faces have swept during growth. They are surfaces generated by the parallel movement of a straight line. When projected parallel to the edge (zone axis) of the two faces 1 and 2 involved, the boundary appears as a straight or somewhat curved line, the (local) direction of which depends on the (instantaneous) relative growth velocity v_1/v_2 of these faces (Sect. 4.3.6 and Fig. 4.14). If v_1/v_2 is constant, the line is straight (i.e., the boundary is planar); if v_1/v_2 fluctuates, the line is irregular, often zigzag-like, as sketched in Fig. 4.8a (i.e., the boundary is an irregularly waved internal surface).

Fig. 4.10 Plate cut from the center of a Czochralski boule of orthorhombic salol ($T_m = 42^\circ\text{C}$), about 1.3 mm thick; imaged length is about 40 mm. The growth striations marking the interface at different stages of growth contain tiny gas bubbles, many of which are sources of growth dislocations. Due to the concave interface the dislocations are focused toward the center of the boule. Due to this effect many dislocations enter the plate from above through the plate surface. Diffraction vector $g(002)$, $\text{CuK}\alpha_1$ radiation

Growth-sector boundaries and their surroundings may be perfect crystal regions. In many cases, however, they are fault surfaces which can be observed by etching, optical birefringence, and x-ray diffraction topography. The fault may be due to increased local impurity incorporation when growth layers on neighboring faces meet at their common edge, or due to slightly different lattice parameters in both sectors. The latter lead to a transition zone along the boundary with lattice distortions which can be detected by the methods mentioned above. An example of this case is shown in Fig. 4.11. Lattice distortions preferentially occur along boundaries between symmetrically nonequivalent faces, due to different incorporation of impurities which leads to slight differences of their

d -values. Boundaries between symmetrically *equivalent* sectors are often strain free, but may be visible by the sharp bends of growth striations (if present), see Fig. 4.9. An illustrative example of the extraordinarily rich growth sectoring of natural beryl, revealed by x-ray topographic imaging of sector boundaries and striations, is presented by Herres and Lang [4.53]. For x-ray topographic characterization of faulted growth-sector boundaries as shift or tilt boundaries, see Klapper [4.7, 8, 54].

The different incorporation of additives in different growth sectors is strikingly demonstrated in the so-called *dyeing of crystals* which goes back to Sénarmont (1808–1862) and was extensively studied in the last two decades by Kahr and coworkers (e.g., [4.29, 30]). They grew crystals from solutions with organic dye molecules as additives. The distinct incorporation of these molecules on different growth faces is conspicuously apparent from the different coloring of their growth sectors (see also Sect. 4.3.5). A similar study of coloring of the growth sectors of KDP with organic dyes is reported by Maeda et al. [4.55].

4.3.3 Vicinal Sectors

Another, less pronounced kind of sectoring frequently arises within the growth sectors treated above, due to growth hillocks (growth pyramids). These very flat *vicinal* pyramids, which are caused by dislocations emerging at their apex, often exhibit facets (*vicinal facets*) deviating by only very small angles from the main growth face. The facets are formed by terraces of growth layers, and their slopes depend on the step height and the widths of the terraces. On facets with different slope angles the incorporation of impurities is different. This leads to slightly distinct d -values of the regions grown on different vicinal facets (*vicinal sectors*). In analogy to growth sectors, the ridges of vicinal pyramids are termed *vicinal-sector boundaries*, which may be faulted surfaces. This also holds for the *valleys* between neighboring vicinal pyramids.

A detailed x-ray topographic study of vicinal sectors and their boundaries formed on {011} dipyrmaid faces and {100} prism faces of KDP and ADP was published by Smolsky et al. [4.56] and Smolsky and Zaitseva [4.57], who also coined the term *vicinal sector*. Atomic force microscope in situ investigation of the step structures of vicinal hillocks in relation to the Burgers vectors of unit and multiple unit height of the dislocations generating the hillocks is presented by De Yoreo et al. [4.58]. Pronounced triangular vicinal pyramids are

Fig. 4.11 (0001) Plate (about 14 mm diameter, 1 mm thick) of benzil grown from solution in xylene, containing faulted boundaries between the growth sectors shown in the drawing. The boundaries are inclined to the plate normal and appear as contrast bands with increased intensity at their emergence from the surface (increased strain due to stress relaxation at the surface). Some boundaries are invisible in the x-ray reflection used here. The plate tapers toward its edges, thus giving rise to *pendellösung* fringes. Some contrasts are due to surface damages. Diffraction vector $g(2020)$, $\text{CuK}\alpha_1$ radiation

observed on $\{111\}$ octahedron faces of potassium alum (cf. the optical and x-ray topographic study by *Shtukenberg* et al. [4.59] and *Klapper* et al. [4.60]). Tetragonal vicinal pyramids generating faulted sector boundaries on $\{001\}$ faces of tetragonal nickel sulfate hexahydrate have been studied by *van Enkevort* and *Klapper* [4.61]. Impurity incorporation on different slopes of vicinal hillocks on $\{111\}$ faces of synthetic diamond has been investigated by *Kanda* et al. [4.62].

Vicinal sectors are usually accompanied by optical inhomogeneities (variation of refractive index, stress birefringence) which can be visualized by sensitive optical polarization means. These inhomogeneities, although usually small, can reduce the threshold for laser damage in high-power optical applications, e.g., in **KDP** crystals used for laser applications [4.63, 64]. Another method of optical visualizing vicinal sectors, by staining with organic dyes (chromophores), was studied in **KDP** by *Zaitseva* et al. [4.65]. The staining was

Fig. 4.12 X-ray topograph of a Z-plate of synthetic quartz cut from the growth sector of a strongly cobbled (0001) face (imaged section about $20 \times 25 \text{ mm}^2$, about 1 mm thick, diffraction vector $g(10\bar{1}1)$, MoK_α radiation). The cobble mounds exhibited a small $\{10\bar{1}1\}$ rhombohedron facet at their steepest side. The planar defects shown in the topograph are formed by the trajectory, during growth, of the groove segments between the hills attached to the facets, and result from increased impurity entrapment. The topographic contrast is stronger at the outcrops of these faults at the plate surfaces (increased strain due to stress relaxation at the surface). Since always the same facet of the three symmetrically equivalent ones was formed, all faults have the same orientation

due to different incorporation of the dye molecules on the distinct slopes of vicinal pyramids: the corresponding sectors appear with coloring of different strengths. A similar study is presented by *Bullard* et al. [4.66], who doped vicinal slopes of potassium hydrogen phthalate during growth from aqueous solution with luminescent organic molecules (fluorophores) and observed the slope pattern by luminescence microscopy. This staining and doping, however, develops during growth and is therefore not applicable to already grown crystals. It is also *destructive* insofar as it increases the degree of imperfection by addition of impurities (see also Sect. 4.3.5).

In this context another similar phenomenon, the very particular growth-cell formation on $\{0001\}$ growth faces of synthetic (hydrothermal) quartz, is noteworthy. The (0001) face is not a habit face according to the Wulff theorem (therefore it never appears on natural crystals), but it is forced to appear when large (0001) seed plates are used in synthetic growth. During growth these faces usually develop a pronounced *cobble* texture (*Lang* and *Miuskov* [4.67]), consisting of rounded hills, which define conical or columnar regions inside the grown crystal. The boundaries between these sectors, defined by the trajectory of the grooves between the *cobbles* during growth, are mostly faulted due to the increased incorporation of impurities. This is particularly the case when habit facets appear on the side of the cobble hill (Fig. 4.12). Moreover, dislocations are trapped into the groove, and thus form part of these boundaries. X-ray topographic studies of these *impurity cell walls* in synthetic quartz, containing dislocations, are presented by *Lang* and *Miuskov* [4.68].

4.3.4 Facet Sectors

These sectors, formed during melt growth on rounded interfaces, are analogous to the growth sectors described above. They arise at the segments of the interface whose orientation coincides with that of a pronounced habit face. This habit face then appears as a planar facet. When growth proceeds, this facet defines inside the crystal a conical or cylindrical region (*facet sector*) whose perfection usually differs considerably from that of the crystal regions grown on the rounded interface (rough growth). This is due to the different modes of growth on rounded and planar interfaces: growth on the latter proceeds from supercooled melt and thus exhibits different (usually higher) incorporation of impurities (dopants) compared with growth on rounded interfaces. This is apparent from the usually much more

pronounced striations in the facet sectors and the lattice distortions along their boundaries.

A favorite method to observe facet sectors and their perfection, in particular in garnets, is by polarized light (stress birefringence), e.g., *Schmidt and Weiss* [4.70] and *Cockayne et al.* [4.71]. An x-ray topography study is given by *Stacy* [4.72]. For a more detailed review on faceting, see Chap. 6 in this Handbook.

4.3.5 Optical Anomalies of Growth Sectors

As discussed above, different growth sectors usually contain different concentrations of impurities, or different deviations from stoichiometry, or – in mixed crystals – different compositional ordering. As a consequence, the physical properties are also – more or less – differ-

ent in different growth sectors. This is conspicuously apparent from the staining of crystals with organic dyes ([4.29,30], and the end of Sect. 4.3.2). In symmetrically equivalent growth sectors the *magnitude* of the property changes is essentially the same, unless the growth conditions at the corresponding faces are different (e.g., due to different hydrodynamics). The different growth directions of equivalent faces, however, lead to different *orientations* of the growth-induced (additional) anisotropies of the properties also for equivalent sectors. This effect can be considered as the reduction of the symmetry of the basic crystal by superposition with the symmetry of the external influence of *crystal growth*, which is represented by a rotational symmetry with polar axis along the growth normal (*Curie principle*, e.g., [4.73, Chap. 3.2]). This *dissymmetry* influences, in principle, all properties, but it is very pronounced for optical refraction due to the high sensitivity of the refractive index to compositional variations and stress. An instructive example is presented in Fig. 4.13, showing the optical anomaly of a (K,NH₄)-alum mixed crystal which is basically cubic, and thus should be optically isotropic [4.59,69]. Here the growth-induced birefringence (*optical anomaly*) is due to a partial ordering of K and NH₄ ions in the {111} sectors [4.59,73].

Optical anomalies of crystals had already been observed and investigated in the early 19th century, as documented in the review by *von Brauns* (1891) [4.74]. A richly illustrated survey, including a historical overview, is presented by *Kahr and McBride* [4.75]. Very recently a monograph has been published by *Shtukenberg et al.* [4.73]. Finally it is mentioned that optical anomalies also occur in vicinal sectors and facet sectors. An interesting example of the former is given by *Zaitseva et al.* [4.65] for large-scale KDP crystals.

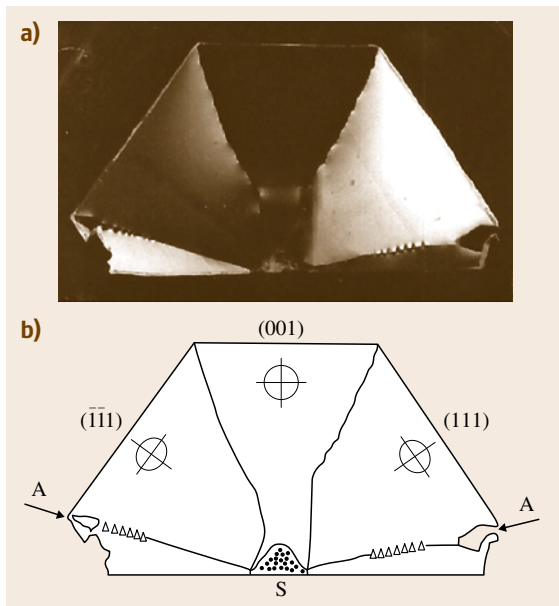

Fig. 4.13 (a) Optical anomaly of a cubic mixed (K,NH₄)-alum crystal grown from aqueous solution, as revealed by polarized light (crossed polarizers): (110) plate, 1 mm thick, horizontal width about 4 cm. (b) Sketch of growth sectors and their boundaries of the plate shown in (a). The {111} growth sectors are optically negative and approximately uniaxial, with their optic axes parallel to their growth directions $\langle 111 \rangle$ (after [4.59]). The (001) sector is nearly isotropic. Along the boundaries A between {111} sectors, small {110} growth sectors (resulting from small periodically appearing {110} facets) have formed during growth. S: seed crystal. After *Hahn and Klapper* [4.69, p. 393] (© 2003 IUCr)

4.3.6 Growth-Sector Boundaries and Relative Growth Rates

As mentioned above, the orientation of the growth-sector boundary is dependent on the relative growth velocity of the two neighboring faces involved. This is illustrated in Fig. 4.14, from which the relation

$$v_1/v_2 = \cos \beta_1 / \cos \beta_2, \quad \text{with } \beta_1 + \beta_2 = \alpha,$$

is easily derived, where α is the angle between the growth directions \mathbf{n}_1 and \mathbf{n}_2 , and β_1 and β_2 are the angles between \mathbf{n}_1 and \mathbf{n}_2 and the growth-sector boundary. The boundary is straight when the relative growth rate is constant; it is curved when it changes. In the latter case the *local* relative growth velocity is derived

Fig. 4.14 Relation between growth velocities v_1 and v_2 of neighboring growth faces (growth directions n_1 and n_2) and the direction of the growth-sector boundary (dotted line)

from the angles β_1 and β_2 between n_1 and n_2 and the tangent plane to the sector boundary in the corresponding growth stage. Thus, the relative growth rates are easily reconstructed if the growth-sector boundary is visible.

An illustrative example, showing the strong changes of the growth velocities (*growth-rate dispersion*) due to fluctuations of growth conditions and defects is presented in Fig. 4.15a,b [4.60, 76], which shows x-ray topographs of a (110) plate cut from a potassium alum crystal (grown from aqueous solution by temperature lowering) which was subjected to temporary redissolution by a temporary temperature increase of about 1 °C [4.27]. The two boundaries between the central cube sector (001) and the two neighboring octahedron sectors ($\bar{1}11$) and ($1\bar{1}1$) are clearly depicted by kinematical contrast due to lattice distortions. (For the contrast variations in different x-ray reflections, see Chap. 42 in this Handbook.) Figure 4.15c outlines the shape of the crystal in different stages of growth, reconstructed from the course of the growth-sector boundaries (dotted line). Four regions (1–4) of different relative growth rates can be distinguished. In the first period, after seeding-in, the crystal was grown by continuous temperature decrease of about 0.3 °C/day until it reached the shape outlined by A–A–A–A. At this stage the temperature of the growth chamber was increased in one step by 1 °C. Due to the slow transfer of the temperature jump into the solution, redissolution started about half an hour later, recognized by the rounding of the crystal edges. Now the previous temperature and decrease rate were restored and growth continued as before. Due to this disturbance a layer of liquid inclusions covering a part of the (001) facet was formed, and its growth rate, rel-

ative to the neighboring {111} faces (the growth rate of which remained constant during the whole experiment), was strongly increased in region 2; in regions 3 and 4 it decreased again. From the angles β_1 and β_2 ($\alpha = 35.26^\circ$) the relative growth rates were determined as

$$v(001)/v(111) = 1.0/5.6/1.7/0.8$$

in growth intervals 1/2/3/4

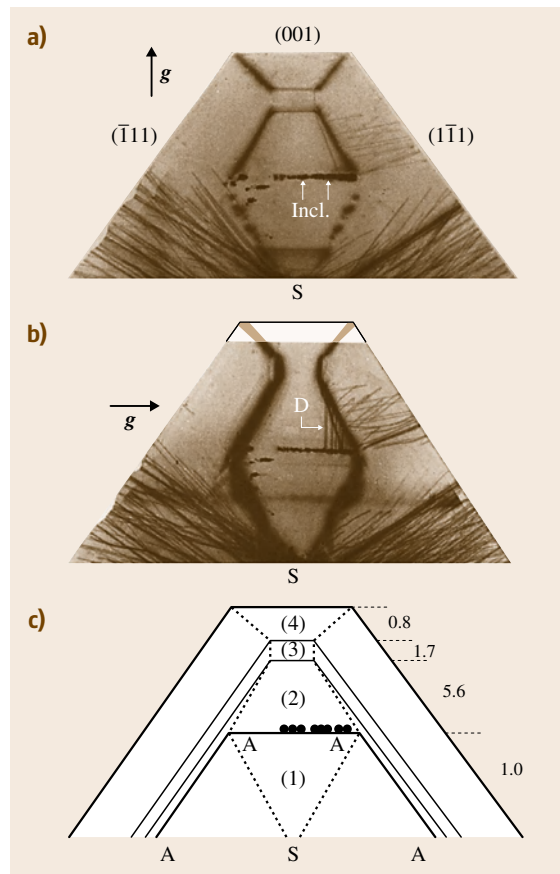

Fig. 4.15a–c Sections of topographs of a (110) plate cut from a potassium alum crystal subjected to a temporary redissolution (vertical extent 12 mm, reflections 004 (a) and 220 (b)). S: location of the seed (outside the section); Incl.: liquid inclusions; D: edge dislocations. (c) Illustration of the development of the crystal shape and of growth-sector boundaries (dotted lines) during growth. Contour A–A–A–A outlines the shape of the crystal at the time of redissolution. At the right side the relative growth rates $v(001)/v(111)$ of growth intervals 1–4 are given (after [4.76])

(averaged over the nearly equal left- and right-hand sides). The drastic increase in period 2 is obviously due to the dislocations D originating from the inclusions, and the retardation in periods 3 and 4 may arise from the elimination of these dislocation from the (001) face by bending at the growth-sector boundary into the (111) sector. Note that only part of the dislocations involved in this process is visible in the topographs (Fig. 4.15a,b) of the 1.4-mm-thick crystal cut, since the larger part

of the (001) sector (with a basis of about $8 \times 8 \text{ mm}^2$ in growth stage A–A–A–A) is outside the cut and thus not recorded. In this context reference is made to similar and more detailed studies on dislocation-dependent growth rate dispersion of {100} and {110} growth faces of potassium alum by Sherwood and Shiripathi [4.77], Bhat et al. [4.78], and Ristic et al. [4.79]. An interesting output of their investigations is evidence for the growth-promoting role of pure edge dislocations (Sect. 4.4.7).

4.4 Dislocations

4.4.1 Growth Dislocations and Postgrowth Dislocations

Dislocations are generated during crystal growth, by plastic deformation and by the condensation of self-interstitials and vacancies. In the study of crystal growth defects it is useful to distinguish between two categories of dislocations:

1. Dislocations which are connected with the growth front and proceed with it during growth (*growth dislocations* or *grown-in dislocations*)
2. Dislocations which are generated *behind* the growth front, either still during the growth run or during cooling to room temperature (*postgrowth dislocations*), or later during processing or by improper handling.

The final arrangement of dislocations in a crystal at room temperature results from growth dislocations, postgrowth dislocations, and the movement, multiplication, and reactions of both after growth. Crystals grown at low temperatures (e.g., from aqueous solution) and in their brittle state usually contain dislocations in their original *as-grown* configuration, whereas in crystals grown at high temperatures, the original dislocation configurations may be drastically altered by dislocation movement, dislocation multiplication, and dislocation reactions. These processes, which may occur during the growth run (*behind* the growth front), are induced by thermal stress due to temperature gradients and, particularly in crystals grown at very high temperatures, by the absorption of interstitials and vacancies (*dislocation climb*).

In this chapter the formation and propagation of dislocations in crystals grown at low temperatures (below 100°C) under zero or only low thermal gradients are treated. The development of dislocation configurations

during growth from melt under high thermal gradients or during processing at elevated temperatures has been experimentally and theoretically studied by various authors (e.g., [4.80–83]) and is reviewed in Chap. 6 of this Handbook.

4.4.2 Sources of Growth Dislocations

For topological reasons dislocation lines cannot start or end in the interior of a perfect crystal. They either form closed loops, or they start from external and internal surfaces (e.g., grain boundaries), or from other defects with a *break* of the crystal lattice. In crystal growth, such defects may arise from all kinds of inclusions (e.g., foreign particles, liquid inclusions, bubbles, solute precipitates). When inclusions are overgrown and *closed* by growth layers, *lattice closure errors* may occur. These errors are the origin of growth dislocations which are connected to the growth front and propagate with it during further growth.

It is a very common observation that inclusions are the source of growth dislocations. Examples are shown in Figs. 4.3, 4.5, 4.10, etc. The appearance of dislocations *behind* an inclusion (viewed in the direction of growth) is correlated with its size: small inclusions emit only a few dislocations or are often dislocation free. Large inclusions ($> 50 \mu\text{m}$) usually emit bundles of dislocations. In some cases, however, large inclusions (several millimeters in diameter) of mother solutions *without* dislocation generation have been observed (e.g., in the capping zone of KDP [4.84, 85]).

The generation of growth dislocations by foreign-particle inclusions has been experimentally studied by Neuroth [4.86] in crystals growing in aqueous solution (potassium alum) and in supercooled melt (benzophenone $(\text{C}_6\text{H}_5)_2\text{CO}$, $T_m = 48^\circ\text{C}$; salol $\text{C}_{13}\text{H}_{10}\text{O}_3$, $T_m = 42^\circ\text{C}$). A seed crystal is fixed to a support in

such an orientation that a dominant growth face [octahedron (111) for cubic potassium alum, prism (110) for orthorhombic benzophenone, pinacoid (100) for orthorhombic salol] develops horizontally. After a sufficiently long distance of (visually) perfect growth, a small ball of solder (0.3–0.5 mm) is placed on the horizontal growth face, and growth continued without change of conditions. During the whole experiment the growth surface was observed with a microscope (long focal distance) in reflected light or by Michelson interferometry, both with videotape recording. After the deposition of the ball the face grows slowly as before without additional surface features as long as the ball is not covered by growth layers. During this period the crystal seems to *sink* into the growing crystal. In the moment when the ball is covered by growth layers, a conspicuous, fast extending growth hillock appears, emitting macrosteps from its apex. After some time of growth the originally single hillock splits into a group of diverging hillocks. This indicates that a bundle of dislocations, fanning out during growth, has been created by the ball inclusion (Fig. 4.16).

Fig. 4.16 X-ray topograph of a (010) plate (about 1.5 mm thick, width 21 mm) cut from a crystal of orthorhombic salol grown in supercooled melt. It contains a solder ball (diameter about 0.4 mm) dropped on a perfectly growing (100) facet (directed upward). Numerous dislocations were generated *behind* the ball. Dislocations of the fan propagating to the left are pure screw and exactly parallel to one of the prominent $\langle 101 \rangle$ edges which dominate the shape of the crystal (cf. *Deviations from Calculated Directions* (i) in Sect. 4.4.4 and Fig. 4.22). The (unresolved) dislocations of the vertical bundle have Burgers vectors $[100]$ and $[001]$. Diffraction vector $g(200)$, $\text{CuK}\alpha_1$

For the study of the dislocations associated with the inclusions, a plate containing the ball and the region *behind* it was cut out of the crystal and subjected to x-ray topography. Figure 4.16 shows that – in accordance with the observed surface pattern – numerous dislocations originate from the *back side* of the ball. Their density is partially too high to be resolved by this imaging method.

Similar experiments have been performed with mechanical in situ violation (puncturing, scratching) of an interface perfectly and steadily growing in solution, supercooled melt, and by Czochralski pulling [4.86]. Again, bundles of dislocations originate from these damages, which in solution growth frequently give rise to liquid inclusions. In plastic crystals (always the case in melt growth) the mechanical impact generates glide dislocations which emerge at the growth front and continue as growth dislocations. Similar experiments are reported by Forty ([4.87, esp. p. 23]). His review presents a rich collection of photographs of growth spirals and other surface patterns on growth faces of various crystals.

The formation of screw dislocations in thin plates of organic crystals during growth from solution and from the vapor has been studied in situ by Russian authors using (polarized) light microscopy with film recording [4.88–90]. Screw dislocations arise at reentrant corners between branches of dendrites [4.88] and by growth around intentionally introduced particles [4.89, 90]. In these cases the dislocations run through the lamellae and do not end inside the crystal. The mechanism of formation of lattice closure errors and of dislocations *behind* an inclusion on the nanometer scale is not yet fully understood, although simple models have been derived. An example is presented by Dudley et al. [4.91].

As pointed out in Sect. 4.4.2, in habit-face crystals inclusions preferentially arise in the regeneration zone of growth on rounded interfaces, in particular in the zone of first growth on a seed crystal. Moreover, dislocations and other defects (grain boundaries, twins) preexisting in the seed will continue into the growing crystal. Thus, the perfection of the seed as well as the seeding-in process are most crucial for the growth of perfect crystals. This holds for all methods of seeded growth, not only for habit-face crystals. That the regeneration zone around the seed crystal is the main source of dislocations is apparent from several topographs shown in this chapter (e.g. Figs. 4.19, 4.21 and 4.24). It is stressed that inclusions and dislocations can largely be avoided by very slow (and thus time-consuming)

growth during the regeneration period of first growth on a perfect seed.

Finally it is emphasized that inclusions can also block already existing dislocations. This has been observed several times by the author, and reported in the literature. It frequently happens to dislocations in the seed crystal which are blocked by inclusions formed in the regeneration zone (*capping*) of first growth and do not enter the growing crystal [4.84,85]. Thus provoking a capping zone by an intentionally introduced deviation of the seed surface from a habit face may be helpful for reducing the number of dislocations coming from the seed, but it implies also a considerable risk of generating *new* dislocations behind the inclusions. The blocking of growth dislocations by closed inclusions must obey the conservation law of Burgers vectors, as discussed below in Sect. 4.4.3.

4.4.3 Burgers Vectors, Dislocation Dipoles

The sum of the Burgers vectors of all dislocations originating from an inclusion fully embedded in an otherwise perfect crystal is zero [4.84]. This directly follows from Frank's conservation law of Burgers vectors (see textbooks on dislocations, e.g., [4.92–94]), which states that the sum of Burgers vectors \mathbf{b}_i of all dislocation lines going into a dislocation node (i. e., with line direction *into* the node) is zero $\sum \mathbf{b}_i = 0$ (analogous to Kirchhoff's law of electrical currents). Another proof may be given via the Burgers-circuit definition of Burgers vectors (e.g., [4.92–94]): imagine a Burgers circuit parallel to the growth face in the perfect crystal region grown before the inclusion was formed. Now shift the circuit stepwise in the growth direction over the inclusion and the dislocation bundle behind it. No closure error of the circuit, which now encircles all dislocations, will arise during this (virtual) procedure: $\sum \mathbf{b}_i = 0$.

From this it immediately follows that a *single* dislocation cannot originate from an inclusion. If dislocations are formed, there must be at least two of them, with opposite Burgers vectors. This is often observed when the inclusions are very small. Two slightly diverging dislocation lines emanating from small, x-ray topographically invisible or nearly invisible inclusions were observed in KDP by Fishman [4.84]. Examples are presented in Fig. 4.19 (label A) for salol grown from supercooled melt. A few pairs of slightly diverging dislocations, starting from a point, can also be recognized in Fig. 4.10 of a Czochralski salol specimen. There are, however, many x-ray topographic observations of apparently only one dislocation line arising from an in-

clusion (e.g., in Fig. 4.3, where only one wider contrast line indicates the presence of more than one dislocation). In all these cases the single lines must represent pairs of two closely neighboring (x-ray topographically unresolvable) parallel dislocations with opposite Burgers vectors: a dislocation dipole. Such a dipole can alternatively also be considered as a single dislocation in the shape of a narrow hairpin with its (virtual) bend in the inclusion. In this approach the two branches of the *hairpin* have the same Burgers vector, but opposite directional line sense. Examples of a pure-screw and two pure-edge dislocation dipoles are shown in Fig. 4.17. The two branches of the dipoles attract each other and may annihilate if they come close enough together. This annihilation is possible for screw dislocation dipoles, and for edge dipoles if both edge dislocations of the latter are on the same glide plane. If they are located on

Fig. 4.17a–c Sketches of dislocation dipoles originating from an inclusion. Here a dipole is considered a single (hairpin) dislocation with Burgers vector \mathbf{b} but opposite line direction sense of the two branches. (a) Pure-screw dipole; (b,c): pure-edge dipoles

Fig. 4.18 Typical geometry of growth dislocations in crystals grown on habit faces. The different preferred directions of dislocations lines within one growth sector result from different Burgers vectors. These directions abruptly change their directions when they penetrate a growth-sector boundary, i. e., when, during growth, their outcrops shift over the edge from one face to the other (i: Inclusions)

different glide planes, the two dislocations can approach each other to a minimum separation, where they have prismatic character and form the edges of stripes of inserted or missing lattice planes (Fig. 4.17b). A model of the formation of a screw dislocation *behind* an inclusion is presented by Dudley et al. [4.91].

During x-ray topographic studies of growth dislocations it is often observed that *only one* contrast line originates from an inclusion, indicating – at first sight – a single dislocation (Fig. 4.3). Here the question arises, how by x-ray topography a dislocation dipole can be distinguished from a single dislocation with the same Burgers vector. If the dipole dislocations are sufficiently separated, they are resolved as two lines or appear as a broader contrast line. However, since the strain fields of the two dislocation have opposite signs and subtract each other, the resultant strain may also be smaller and less extended, if the separation of the two dislocations is small. Thus a dipole may appear on x-ray topographs with similar or even narrower contrast than a single dislocation with the same Burgers vector, and distinction of the two is often not immediately possible. An example is given by van Enkevort and Klapper [4.61, Fig. 11a], where a single contrast line represents a screw dislocation dipole in nickel sulfate hexahydrate, as is proven by the bulge of one of the two dipole arms. In the same crystal the presence of two closely neighboring etch pits at the apices of growth pyramids and slip traces, indicating the escape of one of the two screw dislocations from the hillock center, has been observed. Dislocation dipoles are also formed

during plastic flow of crystals, when the movement of glide dislocations is locally blocked by obstacles (inclusions, jogs; [4.95]). Examples are given in Sect. 4.4.5 (Figs. 4.25 and 4.26).

4.4.4 Propagation of Growth Dislocations

Characteristic Configurations, Theory of Preferred Direction

A dislocation line ending on a growth face will proceed with that face [4.7, 8, 96]. Its direction depends on the shape and orientation of the growth face and its Burgers vector. As shown in Sect. 4.3.2 and Fig. 4.8b, crystal growing on planar (habit) faces consist of growth sectors belonging to different growth faces (different growth directions \mathbf{n}). This leads – under ideal conditions (i. e., stress-free growth) – to a characteristic configuration of growth dislocations which is illustrated in Fig. 4.18. The dislocations start from inclusions and propagate as straight lines with directions \mathbf{l} usually close to, and frequently parallel to, the growth direction of the sector in which they lie. They usually exhibit sharply defined, often *noncrystallographically preferred*, directions \mathbf{l}_0 which depend on the growth direction \mathbf{n} and the Burgers vector \mathbf{b} : $\mathbf{l}_0 = \mathbf{l}_0(\mathbf{n}, \mathbf{b})$. The dependence of the preferred direction \mathbf{l}_0 on the growth direction \mathbf{n} becomes strikingly apparent when the dislocations penetrate growth-sector boundaries. This implies an abrupt change of the growth direction: the dislocation lines undergo an abrupt change of their preferred direction \mathbf{l}_0 (*refraction* of dislocation lines). An example is shown in Fig. 4.19.

These preferred direction of growth dislocations are explained by two approaches [4.7, 8, 96]:

1. *Minimum-energy theorem* (Fig. 4.20a). The dislocation lines adopt a direction \mathbf{l} (unit vector) for which its energy within any growth layer is a minimum. For a growth layer of unit thickness $d = 1$ this can be expressed as

$$E / \cos \alpha = \text{minimum},$$

where $E = E(\mathbf{l}, \mathbf{b}, c_{ij})$ is the elastic energy (strain energy) per unit length of the dislocation line (c_{ij} are the elastic constants of the crystal) and α is the angle between \mathbf{n} and \mathbf{l} . The factor $1 / \cos \alpha$ accounts for the length of the dislocation line in the layer.

2. *Zero-force theorem* (Fig. 4.20b). A dislocation line emerging at the surface experiences an *image* force $d\mathbf{F}$ which depends on the angle α between the dislocation direction \mathbf{l} and the surface normal \mathbf{n} , and on its distance r from the surface. At the surface this

force is infinitely large. According to *Lothe* [4.97] there exists always a direction l_0 for which this force is zero for the dislocation line segments at any depth below the surface. It is plausible that, during growth, a dislocation emerging at the growth face follows this direction of zero force.

Using the formula

$$dF = -\frac{1}{r} \left(\frac{\partial E}{\partial \alpha} + E \tan \alpha \right) dl$$

(*Lothe* theorem [4.97]), it can be shown that both approaches lead to the same preferred directions.

Verification of the Minimum-Energy Approach

The strain energy [4.7,8,96] per unit length of a straight dislocation line is given by (see textbooks on disloca-

Fig. 4.19 Section of a (001) plate (horizontal width about 26 mm, thickness 1.5 mm) cut from a salol crystal grown from supercooled melt. The dislocation lines change their preferred directions when they penetrate the boundaries (arrows) from the {120} sectors into the {010} growth sectors (*refraction* of dislocation lines). A: Dislocation pairs originating from tiny inclusions. Dots: surface damages. Diffraction vector $g(200)$, $\text{CuK}\alpha$

Fig. 4.20 (a) Derivation of the energy of a straight dislocation line within a layer parallel to the growth face. (b) Illustration of the force dF exerted by the crystal surface on a line segment dl of a straight dislocation line emerging at the surface (theorem of *Lothe* [4.97])

tions, e.g., [4.92–94])

$$E = \frac{Kb^2}{4\pi} \ln \left(\frac{R}{r_0} \right),$$

with $K = K(l, l_b, c_{ij})$ the so-called *energy factor* of a straight dislocation line, R the outer cutoff radius, r_0 the inner cutoff radius, and b the modulus of the Burgers vector b . The energy factor K describes the variation of the strain energy with the direction l of the dislocation line. It also depends on the Burgers vector direction l_b and on the elastic constants c_{ij} of the crystal. The inner cutoff radius defines the limit until which the linear elasticity theory is applicable, and it corresponds to the radius of the dislocation core.

Since the logarithmic term and the core energy are, in general, not accessible to a numerical calculation, the variation of strain energy E of a given dislocation with Burgers vector b with direction l is – in a certain approximation – considered as proportional to the energy factor $K(l, l_b, c_{ij})$, assuming the logarithmic term to be independent of l . The energy factor has been cal-

culated using the theory of dislocations in elastically anisotropic crystals developed by Eshelby et al. [4.98]. Since, in general, analytic solutions are not possible, numerical calculations have been performed using the program DISLOC, accounting for the elastic anisotropy of any symmetry down to the triclinic case [4.96]. Figure 4.21a,b shows a comparison of observed and

calculated preferred directions of dislocations with four different Burgers vectors in the (011) growth sector of KDP [4.99]. The agreement is excellent with deviations of 3–6°, except for dislocation 4, the observed directions of which scatter by $\pm 5^\circ$ around a direction deviating by about 20° from the calculated one. This may be due to the very flat minimum of K , which makes the minimum-energy directions more subject to other influences such as surface features and core-energy variations (see *Deviations from Calculated Directions*). Similar comparisons have been carried out for various crystals grown on planar faces from solutions and supercooled melts: benzil, $(\text{C}_6\text{H}_5\text{CO})_2$ [4.54, 100]; thiourea, $(\text{NH}_2)_2\text{CS}$ [4.101]; lithium formate monohydrate $\text{HCOOLi} \cdot \text{H}_2\text{O}$ [4.102]; ammonium hydrogen oxalate hemihydrate, $\text{NH}_4\text{HC}_2\text{O}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$ [4.103]; and zinc oxide, ZnO [4.96]. In general, the agreement of observed and calculated directions is satisfactory and confirms the validity of the above theorems. It is pointed out that the preferred directions are independent of the growth method, provided that the growth faces (growth sectors) are the same. This has been demonstrated for benzil grown *in solution* in xylene and *in supercooled melt* ([4.1], [4.7, p. 138, Fig. 17]). Moreover, basal growth dislocations (Burgers vectors $\mathbf{b} = \langle 100 \rangle$) in prism sectors of hydrothermally grown hexagonal (wurtzite-type) ZnO crystals [4.104] show the same minimum-energy configuration as the corresponding growth dislocations in the prism sectors of benzil [4.96]. This similarity is due to the hexagonal lattice, the same prism growth sector, and

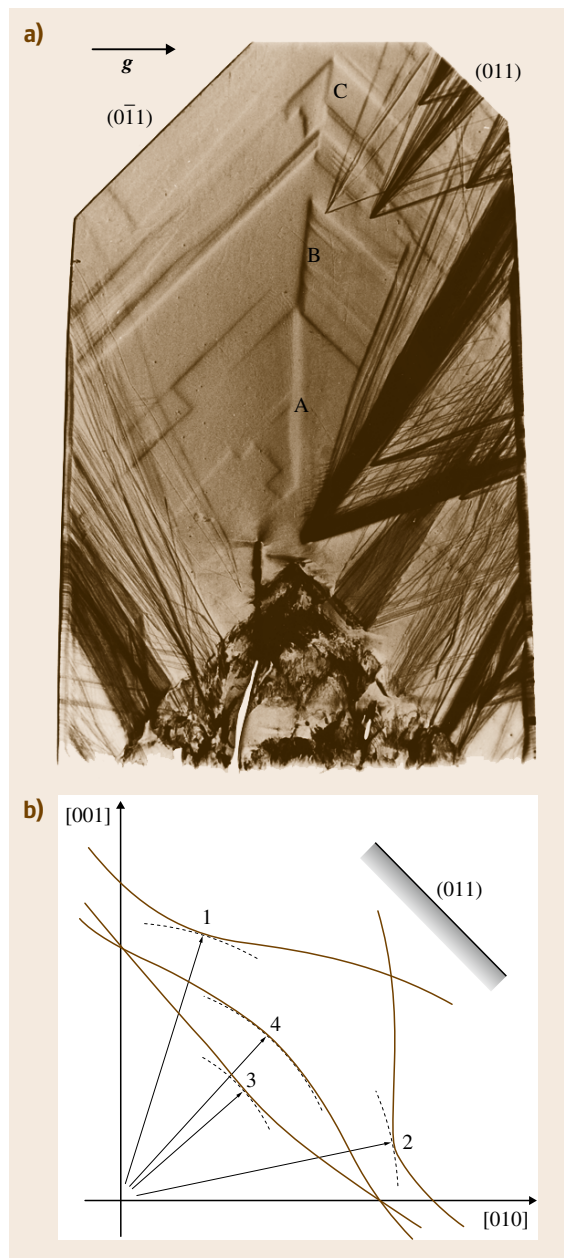

Fig. 4.21 (a) X-ray topograph ($g(020)$, Ag K_α radiation) of a KDP (100) plate (horizontal width ≈ 28 mm, thickness ≈ 1.5 mm), showing bundles of dislocations with noncrystallographically preferred directions emanating from small liquid inclusions (especially in the right-hand (011) growth sector) and from the capping region. The Burgers vectors of these dislocations can be recognized from their preferred directions. In addition, growth bands and features due to vicinal effects are visible. ABC: Boundary between (011) and $(0\bar{1}1)$ growth sectors. (b) Plots of calculated energies $E/\cos \alpha$ (arbitrary units) of dislocations with Burgers vectors $\mathbf{b} = [001]$ (1), $\mathbf{b} = [100]$ (2), $\mathbf{b} = [011]$ (3), and $\mathbf{b} = [0\bar{1}1]$ (4) in growth sector (011) of KDP (polar coordinates: the energies are given by the length of the radius vector to the curves). The preferred directions of minimum $E/\cos \alpha$ are represented by arrows. The dashed lines are circles with radii equal to the minimum values of $E/\cos \alpha$. Note the close coincidence to observed (a) and calculated (b) dislocation line directions ◀

the same Burgers vectors of the dislocations in both cases.

An interesting experimental study of preferred dislocation directions in synthetic quartz is presented by Alter and Voigt [4.105]. They cut (0001) plates (Z-plates) out of different growth sectors of previously grown highly perfect quartz crystals and used them as seed plates for further growth experiments. The seed plates contained growth dislocations following the preferred directions typical for the sector from which they were cut. Since growth now proceeded on the (0001) face, the dislocations of the seed continued into the growing crystals with preferred directions typical of the Z-sector, exhibiting sharp bends of up to 90° at their transition from the seed into the grown crystal. This is instructively shown by x-ray topography [4.105].

On account of the factor $1/\cos\alpha$ in the energy term above, the preferred directions of growth dislocations are mostly normal or nearly normal to the (local) growth face. In some cases of planar interfaces, however, deviations from the growth normal of up to 30° have been observed, in agreement with the calculations.

For interfaces with convex curvature (e.g., in Czochralski growth) the dislocation lines, propagating more or less normal to the growth front, diverge and grow out of the crystal boule through its side faces. For concave interfaces the dislocation lines are focused into the center of the crystal boule (Fig. 4.10). Trajectories of growth dislocations in Czochralski gadolinium gallium garnet (GGG) have been calculated and compared with observed ones by Schmidt and Weiss [4.70]. The curvature of the interface has been taken into account by performing the calculations stepwise in small increments, leading to curved dislocation trajectories. Again the agreement is satisfactory. Moreover, this allowed assignment of Burgers vectors to the different dislocation trajectories which were observed optically with polarized light.

In 1997 and following years, preferred dislocation directions and their bending when penetrating a growth-sector boundary were observed by transmission electron microscopy in GaN grown by metalorganic vapor-phase epitaxy (MOVPE) using the epitaxial lateral overgrowth (ELO) technique [4.106–110]. The GaN hexagonal pyramids {1122} growing through the windows in the mask are in the first stage topped by the (0001) basal plane, which during further growth becomes smaller and finally vanishes. Thus growth dislocations propagating normal to the (0001) facet penetrate the boundary to a {1122} sector and are bent by about 90° into the preferred direction in this sector [4.109]. By this pro-

cess the number of *threading* dislocations is drastically reduced. Very recently the bending of dislocations in growth-sector boundaries has also been used for the elimination of threading dislocations by *aspect-ratio trapping* in Ge selectively grown in submicron trenches on Si substrates [4.111]. Similarly, dislocations are eliminated from prism growth sectors of rapidly grown KDP crystals ([4.112, cf. Fig. 4]).

The above theory of preferred dislocation directions does not allow a dislocation line to proceed along a growth-sector boundary, as is sometimes discussed: the line would emerge on the edge constituting the boundary and thus be in a labile position. If, however, the edge is a narrow facet, the dislocation line can lie in its sector and appear to proceed along the boundary, but the probability of *breaking out* into one of the adjacent sectors would be high. Ester and Halfpenny [4.113] and Ester et al. [4.114] have observed in potassium hydrogen phthalate V-shaped pairs of dislocations originating from growth-sector boundaries, with the two arms of the V, following sharply defined directions, in the two adjacent sectors. This is in accordance with the minimum-energy concept.

Deviations from Calculated Directions

Although the agreement of observed and calculated directions of growth dislocations is in general satisfactory, frequently discrepancies are found. The reasons for this may be insufficient approximation in the model on which the calculations are based, or by influences of other defects or particular surface relief. The above calculations are based on linear anisotropic elasticity of the continuum and do not account for the discrete structure of the crystals, the dislocation core energy or (in piezoelectric crystals) for electrical contributions.

The following three causes have been found to affect preferred directions:

i. Discrete lattice structure of the crystals and the neglect of the core energy

It is frequently observed that growth dislocations are exactly parallel to a low-index lattice direction (mostly a symmetry direction), although calculations suggest another (usually noncrystallographic) direction. This seems to happen in cases of pronounced Peierls energies, where the dislocations tend to align along the Peierls *energy valleys* (see textbooks on dislocations, e.g., [4.92–94]). It is plausible that dislocations will favor directions parallel to closed-packed directions, strong bond chains, structural channels, and planes of

pronounced cleavage. A dislocation line inclined to such a direction will consist of line segments along this direction, (i.e., lie in the Peierls valley) and kinks or jog across the Peierls potential barrier [4.93, pp. 229–234]. This strongly affects the core energy, which varies considerably with direction, particularly in the neighborhood of the structurally pronounced directions, for which it has a minimum. This is the same effect that leads to those favored directions of, for example, 60° dislocations in diamond- and sphalerite-structure crystals.

An example of the influence of the lattice structure in organic salol grown in supercooled melt and by Czochralski pulling is given in Figs. 4.16 and 4.22, where dislocations with Burgers vectors $\mathbf{b} = \langle 101 \rangle$ align along directions parallel to the prominent crystal edges $\langle 101 \rangle$, independent of the growth directions. A detailed discussion of the competing influences of core energy and elastic

strain-field energy on dislocation directions, based on observations in solution-grown orthorhombic ammonium hydrogen oxalate hemihydrate, is presented by Klapper and Küppers [4.103].

ii. *Long-range stress*

Long-range stress arising near the growth face, e.g., due to other growth disturbances (neighboring inclusions, impurity layers), exerts forces on a dislocation and may locally change the zero-force direction, thus leading to curved dislocations lines.

iii. *Surface relief of the growth face*

Macrosteps sweeping over the dislocation outcrops lead to macroscopic (rounded) kinks in the dislocation lines. A particular influence is exerted by growth hillocks (vicinal pyramids, Sect. 4.3.3), the slopes of which possess an orientation somewhat different from that of the main face. Dislocations emerging from the vicinal slopes exhibit preferred directions different from those outcropping on the main face. Similar to the *refraction* of dislocation lines at growth-sector boundaries (Fig. 4.19), dislocation lines change their directions when they pass through an intervicinal boundary, i.e., when their outcrops shift from one vicinal facet to another. The influence of the surface relief, in particular of vicinal slopes, on the course of dislocations has been studied by Smolsky and Rudneva [4.116] and Smolsky et al. [4.48].

An example of the influence of vicinal pyramids on the course of growth dislocation lines is presented in Fig. 4.23. Here the dislocation lines in the right and left $\{011\}$ sectors of KDP change their directions when they pass through the boundaries appearing in the topograph as dark and white contrast bands roughly parallel to the traces of the $\{011\}$ faces. These boundaries are assumed to result from the competition of different growth pyramids. A dominating vicinal pyramid may be *overrun* by another pyramid which now takes over the dominating role. Since this overflowing of one growth pyramid over another can take place within a short growth period, the boundaries between regions grown on one or the other pyramid are practically parallel to the *main* growth face. Due to the different inclinations of the pyramid facets, the preferred directions of dislocations ending on these slopes are different.

Determination of Burgers Vectors

In x-ray topography, Burgers vectors are usually determined with the aid of the $\mathbf{g} \cdot \mathbf{b}$ criterion (*visibility rules*, see Chap. 42 of this Handbook). This requires

Fig. 4.22 Section (about $11 \times 11 \text{ mm}^2$) of a (010) plate (about 1.3 mm thick) cut from the cone region of a Czochralski salol crystal (pulling direction $[100]$ upward; S: seed crystal, broken off). The topograph shows many straight dislocation lines ($\mathbf{b} = \langle 101 \rangle$) exactly parallel to $\langle 101 \rangle$, which is the most prominent morphological edge of the crystal (Fig. 4.16). This direction is enforced by the discrete lattice structure, because the minimum-energy continuum approach suggests directions close to the normal to the concave interface. Furthermore, reactions (segment-wise annihilation) with a few *vertical* dislocations are recognized (after [4.115]). Diffraction vector $\mathbf{g}(200)$, $\text{CuK}\alpha_1$

the imaging of dislocations in several, at least two, different reflections, and sometimes an unambiguous determination is not possible with this method. Since the preferred directions of dislocation lines in a growth sector are characteristic of the Burgers vector, the observation of such directions may provide information on the Burgers vector direction. This should be particularly successful in cases where the dislocations penetrate a sector boundary, so that preferred directions of the same dislocation in different growth sectors are observed.

Depending on the knowledge of the elastic constants and the availability of a computer program the following three options are considered:

- a) If in a crystal the Burgers vectors and corresponding preferential directions of dislocations in a growth sector have been determined by application of the

visibility rules, then in further x-ray topographic studies of the same crystal species the Burgers vectors of these dislocations can be identified by their preferred direction \mathbf{l}_0 without necessarily taking exposures in different reflections.

- b) If the elastic constants of the crystal under investigation are known and if a computer program is available, the directions \mathbf{l}_0 may be calculated for various Burgers vectors and growth sectors and compared with the observed ones. This may be particularly helpful in cases where unambiguous identification of the Burgers vector direction by the visibility rules is not possible.
- c) Apart from these possibilities, the following three general statements, derived under the assumption that the energy factor K_s of a pure-screw dislocation is minimal and that K_e of a pure-edge dislocation is maximal (which is usually the case), may be useful [4.103]:

1. If $\mathbf{b} \parallel \mathbf{n}$, then $\mathbf{l}_0 \parallel \mathbf{n}$ (pure-screw dislocation normal to the growth face)
2. If $\mathbf{b} \perp \mathbf{n}$, then $\mathbf{l}_0 \parallel \mathbf{n}$ (pure-edge dislocation normal to the growth face)
3. If \mathbf{b} is inclined to \mathbf{n} , then \mathbf{l}_0 lies between \mathbf{n} and \mathbf{b} .

In case 1 the energy per unit growth length $E = K / \cos \alpha$ (see *Characteristic Configurations, Theory of Preferred Direction*) has a steep minimum, because both K and $1 / \cos \alpha$ (i. e., the length of the dislocation line in the unit growth layer) have a minimum along \mathbf{n} , whereas in case 2 K is maximal and $1 / \cos \alpha$ is minimal. In the latter case \mathbf{l}_0 is parallel to \mathbf{n} only if the decrease of K with increasing α is overcompensated by the increase of the length $1 / \cos \alpha$ (which is mostly the case), leading to a flat minimum of E along \mathbf{n} . In case 3 the minima of K (along \mathbf{b}) and of $1 / \cos \alpha$ (along \mathbf{n}) have different directions, thus the minimum direction \mathbf{l}_0 of E lies between them (i. e., it deviates from the growth direction \mathbf{n} towards the Burgers vector \mathbf{b}).

These three rules have proved to be obeyed in most cases studied [4.54, 99–103]. Exceptions are provided by those dislocations whose directions are predominantly influenced by the discrete lattice structure. An application and detailed discussion of these rules for Burgers vectors of dislocations in orthorhombic ammonium hydrogen oxalate hemihydrate is reported in [4.103, p. 502].

Fig. 4.23 X-ray topograph ($g(020)$, $\text{AgK}\alpha$ radiation) of a (100) plate of KDP (horizontal width 26 mm, about 2 mm thick) showing growth dislocations in two {011} growth sectors. The preferred directions are modified by the varying vicinal surface relief on the {011} growth faces

4.4.5 Postgrowth Movement and Reactions of Dislocations

The as-grown geometry of dislocations with preferential directions, described in the previous sections, may be more or less drastically changed by thermal stress during cooling to room temperature [4.7–11]. Crystals grown in their brittle state from solution are rather in-

sensitive in this respect. An example is benzil grown at about 40 °C from a solution in xylene by slow solvent evaporation (Fig. 4.24a): its growth dislocations are sharply straight-lined with preferred directions [4.7, 54, 100]. Even the thermal stress, which occurred by uncontrolled cooling and which induced a crack, did not change the grown-in dislocation configuration.

Crystals growing from their melt are always in the plastic state, and therefore their dislocations are subject to plastic glide even under small stress. As already mentioned in Sect. 4.1, gradient-free growth is possible from supercooled melt [4.1], and grown-in dislocation configurations can be preserved if the crystal is cooled very slowly to room temperature. This has been shown for benzil grown from slightly supercooled melt ($T_m = 96^\circ\text{C}$) and carefully cooled through its plastic zone into its brittle state: the grown-in dislocations are straight-lined and exhibit essentially the same geometry as that in crystals grown from solution ([4.1] and [4.7, Fig. 17]).

If stress arises during growth from the melt or during cooling through the plastic zone, the grown-in dislocations move and adopt a more or less irregular arrangement. This is shown in Fig. 4.24b, which presents a topograph of benzil grown from the melt with supercooling of about 0.5 °C. It shows numerous growth dislocations originating from the strongly disturbed zone of first growth on the seed crystal. Many of them follow irregular courses. They often exhibit straight-line segments along directions $\langle 100 \rangle$ (which are twofold-symmetry axes in the basal plane (0001) of the trigonal crystal), indicating the influence of the discrete lattice structure, and pinning points where dislocation movement was locally stopped by obstacles. Line elements parallel to the growth faces are also present. They cannot have formed in this orientation at the growth face, because the strong force at the surface would have pushed parallel segments out of the crystal or rotated them into an orientation of low or zero force (see the Lothe theorem above). This argues that the growth dislocations must have changed their course after growth, probably when the crystal was taken out of the melt. For this procedure the growth chamber was shortly opened whereby cool air flowed against the crystal. There are, however, also straight dislocations (pure-edge) normal to the growth faces, still following the preferred directions suggested by the minimum-energy theory.

Figure 4.25 shows, among others, four growth dislocations (arrows a) in orthorhombic benzophenone, grown in supercooled melt, which exhibit line segments with sharply defined noncrystallographic preferred di-

Fig. 4.24 (a) (0001) Plate (horizontal width 28 mm, thickness 1.2 mm) cut from a trigonal benzil crystal grown in its brittle state at about 40 °C from a solution in xylene by solvent evaporation. S: seed crystal, containing a crack which was formed at the end of the growth run. (The crack tips on the right and left sides of the seed induce extended long-range strain.) All dislocations are straight-lined with preferred directions. Diffraction vector $g(2020)$, $\text{CuK}\alpha_1$. (b) (0001) Plate (horizontal width about 35 mm, thickness 1.2 mm) cut from a crystal grown in its plastic state from a supercooled melt ($T_m = 96^\circ\text{C}$). Numerous growth dislocations start from the surface of the rather strongly disturbed seed S, and many of them show post-growth movement. $g(02\bar{2}0)$, $\text{CuK}\alpha_1$

rection (mainly screw character, Burgers vector $[001]$ vertical) and segments subjected to postgrowth movement. The latter consist of several bows generated by dislocation movement which was locally hindered by pinning points. The horizontal line segments d are pure-edge dislocation dipoles (Sect. 4.4.3). Note that these dipole segments, consisting of two closely neighboring edge dislocations with opposite Burgers vectors, exhibit mostly about the same and in some cases wider and stronger x-ray topographic contrast, compared with the single dislocation lines. Similar observations of postgrowth movement of growth dislocations with pinning points forming dipoles were made for sodium chlorate

Fig. 4.25 Section (about $4 \times 7 \text{ mm}^2$) of a (110) plate (about 1.5 mm thick) of benzophenone grown from supercooled melt. The arrows a mark four growth dislocation in a (111) sector showing sharply defined noncrystallographically preferred directions (predominantly screw character) in their upper, and postgrowth movement with pinning stops in their lower, parts. Burgers vector $b = [001]$ vertical. The horizontal segments are pure-edge and form a few dislocation dipoles (arrows d). The dislocations emerge through the plate surfaces. $g(002)$, $\text{CuK}\alpha_1$

Fig. 4.26 Section ($3.8 \times 8.0 \text{ mm}^2$) of a plate (thickness about 1.2 mm) cut from a Czochralski crystal (pulling direction upward) of benzophenone ($T_m = 48^\circ\text{C}$), showing growth dislocation after postgrowth movement. The pinning points of one of the dislocations at the right-hand side mark its originally straight course. At the left side some dislocations have partially annihilated and formed closed loops. $g(002)$, $\text{CuK}\alpha_1$

NaClO_3 and lithium ammonium sulfate LiNH_4SO_4 . This finding is remarkable insofar as these two crystals appear, by microhardness indentations, as highly brittle, forming cracks even under lowest indentation loads. This indicates that in these crystals fast plastic flow is impeded by high friction but slow dislocation movement (creep) is possible.

An even more drastic change of growth dislocations is presented in Fig. 4.26, which shows a section of a plate cut out of the center of a Czochralski-grown benzophenone crystal (temperature of the melt about 1.5°C above $T_m = 48^\circ\text{C}$, pulling rate 20 mm/day). During pulling the crystal was cooled by blowing air of about 35°C against the rotating crystal in order to obtain a crystal diameter of 25 mm [4.42]. The topo-

graph shows growth dislocations which originate from the zone of first growth on the seed crystal (outside the top of the figure). A few of the dislocations have retained their original course (straight or slightly curved lines), but most of them have suffered postgrowth movement (which may have occurred already during the pulling process): they consist of a series of bow-shaped segments connected at pinning points (right-hand side of Fig. 4.26). The pinning points are aligned along straight lines marking the original position of the dislocations. On the left-hand side of Fig. 4.26 the changes are even more drastic: some dislocations have partially annihilated, leaving behind only a few large and several small dislocation loops. Postgrowth reactions of growth dislocations forming dislocation nodes in Czochralski salol have been studied by *Neuroth and Klapper* [4.115].

Interestingly, the dislocations in the Czochralski salol of Fig. 4.10 have preserved their growth configuration with straight lines roughly normal to the growth front, despite the thermal stress which is always present in this growth technique. This may be due to the low growth temperature ($T_m = 42^\circ\text{C}$) and the narrow plastic zone of salol below the melting point.

4.4.6 Postgrowth Dislocations

Dislocations formed in the interior of already grown crystal without connection to the growth front or other surfaces must be closed loops [4.7–11]. It is practically impossible to generate closed loops in a perfect crystal by stress, since the stress required for such processes would be extremely high. Inclusions, however, usually represent stress centers and form internal surfaces in the crystal. The stress in the crystal around the inclusions is relieved by the emission of concentric dislocations loops or – more frequently – of dislocation half-loops. The half-loops are – strictly speaking – also closed loops with a virtual closing line element inside the inclusion. Half-loops can also generate growth dislocations: if stress is built up around an inclusion just incorporated and still close to the growth front, half-loops emitted from the inclusion may *break through* to the growth interface, whereby each half-loop forms two separate dislocation lines with opposite Burgers vectors propagating with the growth front. Dislocation half-loops emitted from bubble inclusions and from decomposition particles in benzil grown from supercooled melt are shown in Fig. 4.27a,b. Examples of half-loops in solution-grown crystals, revealed by x-ray topography, are given in [4.9] (sodium chlorate)

and [4.117] (tetraoxane). The latter study shows the successive emission of half-loops from inclusions and their splitting into two separate dislocations when reaching the crystal surface. A very peculiar kind of dislocations loops is found in octadecanol crystals grown from xy-

Fig. 4.27 (a) Postgrowth dislocation half-loops in benzil (grown from supercooled melt) emitted from a trail of bubbles. Section $4.5 \times 5 \text{ mm}^2$ of a $(01\bar{1}0)$ plate (after [4.1]). The dislocations belong to the $\{01\bar{1}0\}\langle 100 \rangle$ glide system and are pure-screw in their horizontal segments. $g(20\bar{2}0)$, $\text{CuK}\alpha_1$. (b) Section (about $9.5 \times 8 \text{ mm}^2$) of a (0001) plate of benzil grown from supercooled melt, showing dislocation loops of glide system $(0001)\langle 100 \rangle$ emitted from small inclusions. The loops are elongated in the direction of their (symmetrically equivalent) Burgers vectors $b = [100]$ and $[110]$; the loops with the third equivalent Burgers vector $[010]$ are x-ray topographically *extinct* in the reflection used. $g(02\bar{2}0)$, $\text{CuK}\alpha_1$

Fig. 4.28a,b Forests of hairpin dislocations (screw dipoles) of the easy glide system $(100)[001]$ of orthorhombic thiourea, $(\text{NH}_2)_2\text{CS}$, grown from a water-methanol solution [4.119]. The *hairpins* have invaded the crystal through the $\{101\}$ growth faces due to improper handling after growth. Both topographs $g(001)$, MoK_α . **(a)** Plate (section about $4 \times 6 \text{ mm}^2$) parallel to glide plane (100) , Burgers vector $[001]$ vertical. *Upper-left corner*: growth dislocations penetrating the plate. **(b)** (010) Plate ($7 \times 9 \text{ mm}^2$); the *hairpins* are projected edge-on. *Bottom*: three growth dislocations, liquid inclusions

lene solution: columns of prismatic loops are punched out from inclusions [4.118].

Postgrowth dislocations may also arise from the (external) crystal surface. This is common for growth in contact with a container wall (e.g., Bridgman melt growth). Dislocations are generated by stress due to the different thermal expansion of crystal and container wall or by sticking of the crystal to the wall. An illustrative example is presented in [4.7, Figs. 32 and 33]: it shows numerous glide dislocations in cleav-

age lamellae of 2,3-dimethylnaphthalene (grown by the Bridgman method), which arise from the seed region, from the contact with the growth ampoule, from internal stress centers, and from the point of the cleavage impact. In crystals which are plastic at room temperature glide dislocations may invade through the surface by improper handling after growth, e.g., by mechanical impacts (mechanical polishing, scratches). This is illustrated in Fig. 4.28a,b for orthorhombic thiourea grown from a water-methanol solution. Numerous hairpin dislocations (dipoles) with pure-screw character of their long branches originate from surface damages and extend a few millimeters on the main glide plane (which is also a pronounced cleavage plane) into previously perfect crystal regions [4.119]. In Fig. 4.28b these *hairpins* are projected *edge-on*. The invasion of glide dislocations from the specimen surface into the bulk quite frequently occurs during high-temperature processing of crystals for solid-state electronics and optics (e.g., [4.82]).

4.4.7 The Growth-Promoting Role of Edge Dislocations

Since the pioneering works of *Frank* [4.120, 121] and *Burton, Cabrera, and Frank* (BCF theory) [4.122] it is well established that screw dislocations play a decisive role in growth at low supersaturations by forming persistent step sources in the form of spirals or concentric loops. The latter are generated by pairs of screw dislocations of *opposite* Burgers vectors (screw dislocation dipoles), which separately form spiral hills of *opposite handedness*. These hills fuse into a single growth pyramid with self-perpetuating concentric steps, emitted from the dislocation pair, if the distance between the two dislocations is larger than the critical radius ρ_c of the two-dimensional nucleus for stable growth. For a distance smaller than ρ_c a growth-promoting pyramid is not formed. In contrast to this, a group of N screw dislocations with the *same sign* of Burgers vectors (*same handedness* of growth spirals) increases the growth activity of the face on which they terminate by a factor up to N , if these dislocations are separated by distances smaller than ρ_c (*cooperating spirals*). For distances larger than ρ_c the growth activity corresponds to that of a single screw dislocation (*noncooperating spirals*). These findings hold for all dislocations, normal or inclined to the growth surface, which possess a screw component normal to the growth face [4.122].

Later it was recognized that pure-edge dislocations are capable of generating growth spirals also,

e.g., a pure-edge dislocation, emerging at an angle of about 45° in such a way that its Burgers vector also forms an angle of 45° with the surface, will generate a growth spiral. This has been shown in models by *Strunk* [4.123] and *Ming* [4.124]. In their reasoning, dislocations with Burgers vector *parallel* to the growth surface, e.g., edge dislocations *emerging perpendicularly* from the growth face, were expected *not* to form persistent growth centers promoting growth. There is, however, much experimental evidence proving the opposite. For example, pure-edge dislocations generated by inclusions on {100} cube faces of potassium alum, growing from aqueous solution, drastically increase the growth rate of the {100} face (from which they perpendicularly emerge) in the moment of their appearance. The {100} growth rate is reduced again, when the edge dislocations shift during growth over a crystal edge on a neighboring {111} face (i.e., when they penetrate the boundary into the {111} growth sector [4.76–79], cf. Sect. 4.3.6 and Fig. 4.15). Detailed studies of this growth-promoting effect of edge dislocations in potassium alum are reported in [4.77–79].

The above results show that the term *screw dislocation mechanism* for the formation of growth spirals is not adequate. *Bauser* and *Strunk* [4.125] introduced the terms *longitudinal step source* for growth centers with a Burgers vector component normal to the growth face, and *transverse step source* for growth centers with zero component normal to the growth face. *Frank* [4.126] suggests the terms *rampant step source* and *couchant step source*, respectively, but a final choice of terms has not emerged in this matter.

The probably first demonstration of the growth-promoting effect of *transverse step sources*, based

on a reliable Burgers vector determination, was provided by *Bauser* and *Strunk* [4.125]. They observed, by liquid-phase epitaxial growth on a (100) facet of GaAs, step patterns with well-defined growth centers. High-voltage transmission electron microscopy (TEM) showed that each of these centers was associated with a single dislocation. Burgers vector analysis revealed that, besides hill dislocations *with* Burgers vector components normal to the growth face (*longitudinal* step centers), also those *without* a normal component (*transverse* step centers) occur. Though a statistical analysis is lacking, both types of growth centers seem – in this case – to occur with comparable frequency and activity. *Frank* [4.126] expects that the *transverse growth center* is active only for increased supersaturation approaching the critical value necessary for two-dimensional nucleation, whereas the *longitudinal center* works already for very low supersaturations.

The origin of the activity of transverse step sources is not yet clear. *Bauser* and *Strunk* ([4.125] and references therein) assume that the dislocation is split into two partials (spanning a stacking fault) with a surface step formed between their endpoints on the surface. The growth-promoting activity of this defect arrangement has been demonstrated by *Ming* [4.124]. This approach, however, can only hold for crystals capable of stacking faults. *Frank* [4.126] suggests that surface stress around the dislocation outcrop leads to increased local adsorption of atoms, and *Giling* and *Dam* [4.127] postulate a local roughening of the surface with increased growth, forming a hill which emits from its periphery concentric step rings over the otherwise flat growth face.

4.5 Twinning

4.5.1 Introductory Notes

A twin is a frequently occurring aggregate or intergrowth of two or more crystals of the same species (same chemical composition and crystal structure) with a defined *crystallographic orientation relation* (determining the *orientation states* of the *twin components*), which in mineralogy is called the *twin law*. Besides the twin law, the boundary between twin domains (the *contact relation*) plays a decisive role: twins occur in those crystals in which boundaries of low energy can be formed. This has been proven quantitatively by

Gottschalk et al. [4.128], who showed that the ease and frequency of the formation of (111) spinel twins in the sphalerite (zincblende) structure of III–V semiconductor compounds (GaAs, InP, etc.) is correlated to the (111) stacking-fault (twin-boundary) energy (see also [4.69, p. 422]). There is, however, also a theory which states that the boundary energy is of minor importance and that kinetic influences play a decisive role in the formation of twins [4.129]. This approach, however, is critically discussed [4.130, 131].

Historically, the concept of twinning was developed in mineralogy due to the rich occurrence of morpholog-

ically prominent twins in minerals. In the 1920s another approach, independent of mineralogy, was developed in physics with the investigation of ferroelectricity and ferroelasticity. The spontaneous electric polarization and spontaneous mechanical strain occurring in these *ferroic* crystals lead to ferroelectric and ferroelastic domains which are twin domains as defined in mineralogy. Though the concepts of *twinning* and *domain structures* (as the physical approach is now called) deal with the same phenomenon, there are (apart from a different nomenclature) certain differences: in contrast to *twinning*, the *domain structure* approach requires a (real or hypothetical) *crystallographic parent symmetry* (supergroup), from which the *orientation states* can be derived by a real or hypothetical phase transition. Therefore, this approach cannot be applied to many growth and deformation twins. A comparison of the concepts of *twinning* and of *domain structures* is given by Janovec et al. [4.132] and Janovec and Přívratská [4.133].

Twins are mainly classified by morphological features (dovetail, contact, penetration, sector, polysynthetic twins, etc.), by their genetic origin (growth, transformation, mechanical or deformation twins) and by their lattice coincidence features: *merohedral* twins (full, three-dimensional lattice coincidence), which are also called *twins with parallel axes*, and *nonmerohedral* twins (two or one-dimensional lattice coincidence), also called *twins with inclined axes*. Reviews on twinning are presented in many textbooks of mineralogy and crystallography (e.g., [4.134, 135]). A comprehensive treatment is provided by Hahn and Klapper [4.69, especially section *Growth twinning* p. 412–414]. A survey on x-ray topographic characterization of twinned crystals is given by Klapper [4.6]. In the present section only growth twins and twins generated in the cooling period after growth (postgrowth twins) are treated, whereby emphasis is placed on crystals grown from solutions on habit faces. A treatment of twinning in crystals grown from the melt is presented by in Chap. 6 of this Handbook.

4.5.2 Twin Boundaries

The shape and arrangement of twin domains is essentially governed by the twin boundaries and their preferred orientations. As mentioned in the previous subsection, twin boundaries are contact faces with good structural fit of the twin partners involved, i. e., they are internal surfaces of low energy. Accordingly they are, as a rule, low-index and structurally densely packed lattice planes common to both twin partners. For re-

flection twins and twins by a twofold axis, the twin mirror plane or the plane normal to the twofold twin axis is always an energetically favored contact plane because along this boundary the corresponding lattice planes of the two partners match perfectly. There is, however, a basic difference between *twins with parallel axes* (three-dimensional lattice coincidence: *merohedral* twins) and *twins with inclined axes* (two- or one-dimensional lattice coincidence: *nonmerohedral* twins [4.69, p. 422] [4.132, 133]). In the first case the lattices of the twin components match perfectly along any twin boundary for any twin law. In the latter case the boundary along the common lattice plane of perfect matching is usually strictly adopted. Deviations from strict planarity of these boundaries may occur by steps which form the *twinning dislocations*. These dislocations play an important role in the plastic deformation of crystals by twin formation.

For twins with parallel axes (full lattice coincidence, e.g., for inversion twins) the lattices of the twin components match perfectly along any arbitrary (also curved) boundary. Thus, from this lattice aspect alone, arbitrarily oriented boundaries are expected to occur. A prominent example is the Dauphiné twinning of quartz, which occurs as growth as well as transformation and mechanical (ferrobielastic) twinning: Dauphiné twin boundaries usually follow (at least macroscopically) arbitrary and curved surfaces, whereby low-index boundary segments sometimes also occur [4.136, pp. 75–99]. As a rule, however, low-index twin contact planes are favored also in twins with full lattice coincidence (merohedral twins). An example is given by quartz: Brazil twins (twin law: inversion), which are exclusively growth twins, develop boundaries along low-index planes, preferably parallel to prism and rhombohedron faces [4.136, Fig. 61].

A special case is given by the spinel twins of cubic crystals with twin law *reflection plane* ($\{111\}$) or *twofold axis along* $[111]$. They occur as growth twins in technologically significant crystals with diamond structure (Si, Ge), sphalerite (zincblende) structure (e.g., ZnS, GaAs, InP, and CdTe [4.128, 137]), and sodium chloride structure (photographic materials AgCl and AgBr [4.138–142]). They are characterized by a partial lattice coincidence of $1/3$ of the lattice points (so-called $\Sigma 3$ twins), which form a hexagonal sublattice of the cubic lattice, with the hexagonal axis along the threefold axis $[111]$ common to both twin components. Preferred twin boundaries are planes $\{111\}$ and $\{11\bar{2}\}$ (Fig. 4.29), which are twin reflection planes (in centrosymmetric crystals such as diamond, Si, Ge, AgBr) or planes

Fig. 4.29a–d Spinel twin of cubic crystals with twin mirror plane (111) or twofold twin axis $[111]$ (or alternatively $\pm 60^\circ$ rotation around $[111]$). The domains of the two orientation states are shown *white* and *shaded*. **(a)** Contact twin with (111) contact plane (two twin components). **(b), (c)** penetration twin (idealized) with one (111) and three $\{112\}$ contact planes (12 twin components, 6 of each orientation state) in two different views: **(b)** with one $[001]$ axis vertical, **(c)** with the threefold-symmetry axis $[111]$ common to the two orientation states and coinciding with the twofold twin axis vertical. **(d)** Skeleton of the six components (exploded along $[111]$) of the *shaded* orientation state of **(c)**. The components are connected along one $[111]$ and three $\langle 110 \rangle$ edges meeting in the center

normal to twofold twin axes (in noncentrosymmetric crystals of sphalerite structure, e.g., ZnS, GaAs).

4.5.3 Formation of Twins During Growth

Formation During Nucleation of the Crystal

In many cases, twins are formed already during the first stage of spontaneous nucleation, possibly before the subcritical nucleus reaches the critical size necessary for stable growth. This formation is strongly evidenced for penetration and sector twins, where all domains are of similar size and originate from one common, well-defined *point* in the center of the twinned crystal, which marks the location of the spontaneous nucleus (Figs. 4.29 and 4.30). Other prominent examples are

the penetration twins (two orientation states) in quartz-homeotypic gallium orthophosphate (GaPO_4 [4.47]) and in rhombohedral crystals such as corundum (sapphire, Al_2O_3 [4.143]) or iron borate (FeBO_3 , calcite structure [4.6, p. 390]), and sector twins of pseudo-hexagonal crystals such as lithium ammonium sulfate (Fig. 4.30), potassium sulfate [4.69, p. 408], and aragonite CaCO_3 (Fig. 4.31), which all form twins with three orientation states. The origin of twinning by nucleation must also be assumed for contact twins (Fig. 4.29a), if both partners of the twin have roughly the same size, or

Fig. 4.30a,b Photographs of (001) plates (about 20 mm diameter, about 1 mm thick) of orthorhombic pseudo-hexagonal LiNH_4SO_4 between crossed polarizers, showing sector growth twins. **(a)** Nearly regular threefold sector twin (three orientation states, three twin components). **(b)** Irregular sector twin (three orientation states, but five twin components). After [4.69, p. 413]

Fig. 4.31 (a) Triple growth twin of orthorhombic pseudo-hexagonal aragonite, CaCO_3 . The three twin components are related by two symmetrically equivalent mirror planes (110) and $(\bar{1}10)$. Due to a relatively high deviation from the hexagonal metrics, a gap of 11.4° should be formed. In actual crystal the gap is usually closed, as shown in (b), leading to a strongly disturbed irregular twin boundary

if all spontaneously nucleated crystals in one batch are twinned. For example, *all* crystals of monoclinic lithium hydrogen succinate precipitated from aqueous solution are, without exception, dove-tail contact twins.

An approach to twin formation during crystal nucleation has been advanced by *Senechal* [4.144]. She proposes that the crystal nucleus first formed has a symmetry which is not compatible with the lattice of the (macroscopic) crystal. This symmetry may even be non-crystallographic. It is assumed that, after the nucleus has reached a critical size beyond which the translation symmetry becomes decisive, the nucleus collapses into a twinned crystal with domains of lower symmetry and continues to grow as a twin. This idea of twin formation from noncrystallographic nuclei has been substantiated experimentally by high-resolution TEM (HRTEM) investigations of nanocrystalline diamond-type and face-centered cubic (fcc) crystals, such as Ge, Ag, and Ni [4.145].

Twin Formation by Inclusions

As they are for dislocations (Sect. 4.4.2), inclusions are frequently sources of twins. It is assumed that a nucleus in twinned orientation forms at the inclusion and proceeds in this orientation during further growth. An instructive experimental key study of this process is presented by *Sunagawa* et al. [4.146] for Dauphiné and Brazil twins in synthetic amethyst quartz. Amethyst quartz contains much more Dauphiné and, to a still higher extent, Brazil growth twins than normal (colorless) quartz. The higher frequency of twin formation is doubtlessly due to its relatively high content of iron [4.147]. *Sunagawa* et al. [4.146, and references

therein] grew amethyst quartz hydrothermally in various solutions containing ferric iron, on amethyst seed plates of various orientations. They studied the twinning on as-grown faces, on etched growth faces, and on cut surfaces by light-microscopic methods. In all cases the Dauphiné and Brazil twins originated from solid inclusions containing iron (probably as goethite, FeOOH). In some cases the Brazil twins are associated with dislocations originating from the same inclusion.

A twin component originating from an inclusion may have the following shapes, depending on the preferred orientation of the twin boundary:

- It forms a conical (pyramidal) insert, embedded in the *mother* crystal, with its apex in the inclusion and widening in the growth direction. This shape occurs, e.g., in quartz for Dauphiné as well as Brazil growth twins, whereby the surface of the twin inserts (i.e., the twin boundary) is rounded for the Dauphiné and faceted by low-index habit planes for the Brazil twin [4.136, Fig. 61]. In amethyst quartz the inserts are lamellae preferably parallel to the major rhombohedron faces.
- For crystals with a pronounced preference of a low-index planar twin boundary, the twin insert is a band-shaped lamella originating from the inclusion and proceeding with the growing crystal. An example is given by hexagonal potassium lithium sulfate (KLiSO_4 , merohedral reflection twin) grown from aqueous solution [4.148].

For the generation of twinning in melt-grown crystals, the reader is referred to Chap. 6 in this Handbook.

Propagation of Twin Boundaries

In contrast to a twin lamella, a (single) twin boundary cannot end *within* an otherwise perfect crystal. Therefore, a twin boundary emerging on a growth face must proceed with it during growth, whereby it should obey the theorem of minimum-energy orientation, postulated in Sect. 4.4 for growth dislocations. This means that the orientation of the twin boundary results from the competition to minimize the area of its surface within a growth layer (i.e., by orienting toward 90° with the grown face) and to minimize the boundary energy per unit area. Since, as a rule, the boundary energy has a pronounced and sharp minimum along a low-index lattice plane (similar to dislocations with pronounced Peierls energy, cf. *Deviations from Calculated Directions*), the boundary will follow this plane even for small angles between the twin contact plane and the growth face.

In mineralogy it is frequently observed that a twin boundary coincides with a large-area prominent growth face. A famous example is the polysynthetic lamellar twinning of the triclinic feldspar albite ([4.69, p. 410]). This indicates that a two-dimensional nucleus in twin position has formed on the growth face of the (previously untwinned) crystal [4.149, pp. 472–475]. Obviously, this process is triggered by defects in the growth face (e.g., by impurities, inclusions). If the twin nucleus spreads out over the growth face, the twin boundary coincides with the growth face. This mechanism seems to be possible only for twin boundaries of low energy, since the boundary energy of the large interface has to be supplied in one step, i.e., during spreading out of one single growth layer in twin position. The energy contribution of the first layer, however, may be quite small, because the structural alteration across the interface occurs only for second-nearest and more distant neighbors, so that the full boundary energy of the twin accumulates only after the deposition of a sufficiently thick package of growth layers. This is particularly the case if long-range (e.g., ionic) interactions are present. Thus, from an energetic point of view, the formation of twin boundaries coinciding with growth faces – after a two-dimensional nucleus in twin orientation has formed – appears probable. According to Hartmann [4.150], this kind of twin formation can only occur on *flat* or, with lower probability, on *stepped* faces (F- and S-faces, respectively). The critical step is the formation of the two-dimensional twin nucleus on these faces.

The formation of twin boundaries coinciding with the *actual* growth face, however, seems to be rather the exception, although in special cases, e.g., in polysynthetic lamellar twinning of the albite feldspar, it happens several times within the same crystal. It is pointed out that, for example, the planar low-index boundaries of Brazil twins in quartz *do not* develop parallel to prism or rhombohedron growth faces on which the twins are nucleated, although these faces are preferred (low-energetic) twin contact planes [4.136, 146]. This feature is obviously due to the special character of Brazil twins: they are merohedral inversion twins with full three-dimensional lattice coincidence.

Finally, boundaries of twins with more than two orientation states are considered. Such twins frequently occur in orthorhombic pseudo-hexagonal crystals (e.g., K_2SO_4 , $LiNH_4SO_4$, aragonite $CaCO_3$) and consist mostly of domains of three orientation states (triple twins) related by three equivalent twin mirror planes or twofold twin axes. An example is shown in Fig. 4.30a.

The crystals usually grow as *sector twins* starting from a common nucleus, with three or six twin components. In the latter case pairs of opposite sectors belong to the same orientation state. The twin boundaries mostly coincide with the twin mirror planes, but deviations leading to irregular boundaries may also occur (Fig. 4.30b). A twin boundary may coincide with a growth-sector boundary but usually does not (Fig. 4.30). An x-ray topographic study of pseudo-hexagonal growth twinning in $LiNH_4SO_4$ is presented by Docherty et al. [4.151].

For the sector-twin boundaries of pseudo-hexagonal crystals the angle $\gamma = 2 \arctan(b/a)$ (where a and b are the orthorhombic lattice parameters of the pseudo-hexagonal plane) plays an important role. For an exact fit of the sectors $\gamma = 120^\circ$ is required. Small misfits, e.g., $\gamma = 119.6^\circ$ for orthorhombic lithium ammonium sulfate [4.151] (Fig. 4.30), are tolerated for triple twins without further disturbances, but often induce cracks when the twins grow to a larger size. An example of extreme sectorial misfit occurs in orthorhombic aragonite $CaCO_3$ ($\gamma = 116.2^\circ$), which would generate a gap of 11.4° from the 360° closure. In this case the triple twin usually exhibits two boundaries coinciding quite perfectly with the two twin mirror planes $\{110\}$, whereas the third is irregular and strongly disturbed, thus closing the angular gap (Fig. 4.31b). A particularly interesting example is provided by nanocrystals of germanium nucleated in an amorphous Ge film deposited from the vapor on a NaCl cleavage plane (HRTEM study by Hofmeister [4.145]): pseudopentagonal sector twins by repeated (111) twin reflections and (111) twin contact planes are formed. The angle of one sector is theoretically 70.5° (the supplement to the tetrahedral angle 109.5°) and five of these angles leads to a gap of about 7.5° . This gap is compensated by slight widening of the sectors either by distortion or by the formation of stacking faults within a sector, whereby the five (111) twin boundaries of this fivefold sector twin remain perfect ([4.145] and [4.69, p. 439]).

4.5.4 Growth-Promoting Effect of Twin Boundaries

The growth-promoting influence of twin boundaries forming reentrant edges was already noticed by mineralogists in the 1890s and has later been described in detail by Buerger [4.149] and Hartmann [4.150]. This *twin-plane reentrant-edge effect* (TPRE effect after [4.137]) can occur only in faceted crystals and is pronounced for growth faces adjoining a reentrant edge,

which provides a self-perpetuating step source [4.137, 152–156]. It leads to crystals laterally extended in directions parallel to the twin interface (compared with untwinned crystal) and has also been observed for organic crystals of orthorhombic *n*-alkanes and paraffins [4.157, 158]. The TPRE effect has a particularly strong impact on the morphology of cubic crystals twinned by the spinel law: whereas untwinned cubic crystal exhibits an isometric shape, (111)- and (11 $\bar{2}$)-twinned crystals grow as plates parallel to the twin plane. The growth of (111) and (11 $\bar{2}$) platelets of cubic elemental and compound semiconductors from metal solutions using the TPRE effect has been studied in detail by Faust and John [4.137, and references therein]. Of particular significance for photographic products are tabular crystals of cubic silver halogenides, such as AgBr, AgCl, and AgI. The formation of tabular AgBr crystals by the TPRE mechanism is discussed by Jagannathan et al. [4.138, 139], Bögers et al. [4.140, 141], and more recently Lee et al. [4.156] using the hard-sphere model of Ming and Sunagawa [4.152, 153]. These authors also discuss the effect of two or more *parallel* twin planes (i. e., of twin lamellae).

A more drastic morphological change of cubic crystals is provided by two or more *intersecting* twin planes (*cross-twinning*). In this case the crystals grow as needles parallel to the intersection of the twin planes. Examples are presented and discussed by Wagner [4.159], Hamilton and Seidensticker [4.160] (critically reviewed by van de Waal [4.161]) for Ge (dendrites in $\langle 11\bar{2} \rangle$ direction), and Bögers et al. [4.142] for AgBr and AgCl (needles in $\langle 110 \rangle$ directions).

4.5.5 Formation of Twins after Growth

There are two causes for the formation of twins during cooling to room temperature after growth: phase transitions and ferroelastic switching [4.133].

Phase transition: Crystals often can only be grown at elevated temperatures, where they crystallize in another (*high-temperature*) phase of usually higher symmetry than they adopt at room temperature. On cooling below the transition temperature, twin domains

are formed, whereby the lost symmetry elements of the mother phase act as twin elements (twin laws) relating the twin domains. Examples: lithium niobate LiBO_3 is grown from the melt at $T_m = 1275^\circ\text{C}$ and undergoes a paraelectric–ferroelectric transition at T_c about 1140°C , whereby ferroelectric domains are formed. The high-temperature superconductor $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$, usually grown from flux, is subject to a transition at about 750°C from the tetragonal parent phase into an orthorhombic modification whereby it develops two nearly orthogonal systems of twin lamellae parallel to the two $\{110\}$ mirror planes of the tetragonal mother phase, lost in the transition [4.162]. These lamellae are ferroelastic and can be changed or even removed (detwinning) by mechanical stress. An example related to mineralogy is provided by quartz, which is stable in its trigonal phase below 575°C (α -quartz, point group 32) and hexagonal (β -quartz, point group 622) above this temperature. The transition from the hexagonal to the trigonal modification invariably leads to the formation of Dauphiné twinning (due to the loss of the twofold axis in the sixfold axis). The shape and arrangement of twin domains generated by crystal growth or by phase transformation (e.g., for Dauphiné twins) is quite different. In mineralogy these different features of twin textures are helpful for the determination of the conditions of mineral formation.

Ferroelastic switching: The twin domains of ferroelastic crystals switch by mechanical stress from one orientation state into the other. This occurs quite easily at elevated temperatures where the coercitive stress is strongly reduced. Thus, in a ferroelastic crystal grown without twinning, twin domains may be introduced by stress developed during cooling to room temperature. Here again inclusions forming stress centers are the main reason. The ferroelastic twin pattern is often correlated to the growth defects of the crystal, e.g., with growth striations [4.163, Fig. 100], [4.6, p. 379]. Postgrowth formation of twins by ferroelastic switching has been observed in ammonium sulfate $(\text{NH}_4)_2\text{SO}_4$ [4.151] and Rochelle salt [4.163, p. 184], both grown from aqueous solution.

4.6 Perfection of Crystals Grown Rapidly from Solution

Until the 1980s the opinion prevailed among crystal growers that highly perfect crystals could only be obtained from solution by very slow growth. This has been disproved by the pioneering work of Zaitseva, Smol-

sky, and Rashkovich [4.34, 57], who showed that, by well-devised construction of the growth apparatus and careful pretreatment and strong stirring of the solution, large KDP crystals of high perfection can be grown

from aqueous solution. Their work was the basis of the growth of huge, highly perfect KDP and DKDP crystals of up to 60 cm edge lengths under high supersaturation within a time period of only a few weeks (e.g., [4.17, 35, 36, 164]). The rapid growth of KDP and ADP is described in detail in Chap. 22 of this Handbook. In the present section the growth defects of a slowly grown KDP and a rapidly grown ADP crystal, revealed by x-ray topography, are compared. In addition, the rapid growth of potassium alum, mixed (K,NH₄)-alum, and sodium chlorate [4.165] is reported.

In recent years, various studies of the perfection of rapidly grown KDP crystals have been published, e.g., [4.17, 37, 48, 58]. The most striking difference between slowly and rapidly grown KDP crystals appears in their morphology: crystal grown slowly develops the shape of an *obelisk*, because under low supersaturation, the {100} prism faces are inhibited by impurities so that the crystals grow nearly exclusively on {101} pyramid faces. In order to obtain bulky crystals, large (001) seed plates are used, which lead to a large capping zone (Figs. 4.2, 4.21a, and 4.23). In highly supersaturated and strongly stirred solutions, however, the {110} prism and {101} pyramid faces have essentially the same growth velocity. This allows growth to be started with small *point seeds* with a correspondingly small capping zone. The proper shape and mounting of the point seed and its impact on the habit of the grown crystal has been stud-

Fig. 4.32a,b Typical morphology and dislocation distribution of KDP and ADP crystal (a) slowly grown on a (001) seed plate S and (b) rapidly grown on a *point seed* S. D: dislocation lines, C: strongly disturbed regeneration (*capping*) zone (Figs. 4.21 and 4.23). In (b) this zone is small. *Dashed lines*: growth-sector boundaries. Note that here another (equivalent) labeling of faces is chosen than in Figs. 4.5, 4.21, and 4.23: prism {100}, dipyrmaid {101}

Fig. 4.33 X-ray topograph (MoK α radiation, reflection $\bar{1}01$) of a (010) plate (about 2.5 mm thick, horizontal extension about 60 mm, tetragonal axis vertical) cut from an ADP crystal rapidly grown within 10 days (including the seeding-in process and regeneration period) to a size with {100} edge lengths of about 110 mm. S: Location of the seed. The crystal has grown with about the same growth rates (about 15 mm/day in the end phase) on all {100} and {101} faces. Since the plate was too large for the x-ray topography crystal holder, a part was cut off at the left side. The crystal is highly perfect, as indicated by the x-ray *Pendellösung* fringes (rounded soft contrast bands PL) of constant plate thickness. Only a few dislocations D originate from a liquid inclusion at the point seed (which was out of the x-ray beam). IN: Large liquid inclusions which have formed on the right (100) face due to growth-face instabilities intentionally provoked by decreasing the temperature by 4 °C in one step at 50 °C after about 40 mm of perfect growth. Note that these inclusions have formed on only one of the four prism faces: the four {101} faces stayed also inclusion free. Reflection $g(\bar{1}01)$, MoK α . After [4.165]

ied by Zaitseva et al. [4.112]. The typical morphology of slowly and rapidly grown KDP and ADP crystals, the development of their growth sectors, and the arrangement of dislocations is shown in Fig. 4.32.

The typical growth defects and their distribution in slowly and rapidly grown crystals are apparent from the x-ray topographs shown in Figs. 4.5, 4.21a, 4.23, and 4.33. The crystals shown in the former three figures

were grown in the 1970s in the laboratory of *Bennema* (Delft and Nijmegen, The Netherlands) in a three-vessel growth system [4.26] at constant temperature of about 30 °C and supersaturation of about 5.4% with growth rate of about 1 mm/day on the {101} faces. The crystals were mounted on a tree which rotated in the solution. They contain inclusions, inhomogeneous impurity distributions (in the form of striations, growth, and vicinal sectors), and dislocations. As pointed out already by *Zerfoss* [4.12], *Janssen-van Rosmalen* et al. [4.26, 32], and *van Enckevort* et al. [4.33], liquid inclusions, in particular the quasiperiodic liquid inclusions shown in Fig. 4.5, can be avoided by strong stirring.

An x-ray topograph of an *ADP* crystal rapidly grown in the author's laboratory is shown in Fig. 4.33 [4.165]. The crystal was grown on a point seed in a sealed 10l tank by temperature decrease from 55 to about 45 °C with about the same growth rates on {100} prism and {101} pyramid faces in 10 days to a width of 110 mm along the <100> edges and a height of about 80 mm. It was rotated in the solution on a platform at about 50 cycles/min with reversal of the rotation every 30 s. The rate of temperature decrease was 0.1–1 °C in the generation period and was then increased stepwise to 4 °C/day, dependent on the size of the crystal. It is obvious from Fig. 4.33 that this crystal is much more homogeneous and perfect than the crystals shown in Figs. 4.5, 4.21a, and 4.23. Only a few dislocations originate from the point seed into the prism and pyramid growth sectors. Due to growth

face instabilities, large liquid inclusions have formed on the right prism face, but have healed out perfectly during further growth. Interestingly these inclusions block more growth dislocations than they generate. Convincing proof of the homogeneity of this crystal is the appearance of x-ray *Pendellösung fringes*, which result from the slight thickness decrease toward the edges of the plate. Neighboring (010) crystal plates, not cutting through the seed and through the inclusions, are dislocation free.

Rapid crystal growth of very large, highly perfect crystals from aqueous solution has been reported only for *KDP*, its deuterated variant *DKDP*, and for *ADP* [4.36]. In order to check the applicability of this method to other materials, growth experiments have been carried out with some other compounds usually used in student laboratory courses: pure and mixed potassium and ammonium alums, sodium chlorate, and nickel sulfate hexahydrate [4.165]. The growth procedure was essentially the same as reported above for *ADP*. Apart from some failures due to spontaneous nucleation, large crystals of these materials with edge lengths up to 12 cm could be successfully grown within 7–10 days with growth rates up to 25 mm/day. Optical inspection and x-ray topographic studies indicate that the optical and structural perfection is high and not at all inferior to the quality of corresponding traditionally grown crystals. These results indicate that the rapid growth method is applicable to the growth of many crystals from solution.

5. Single Crystals Grown Under Unconstrained Conditions

Ichiro Sunagawa

Based on detailed investigations on morphology (evolution and variation in external forms), surface microtopography of crystal faces (spirals and etch figures), internal morphology (growth sectors, growth banding and associated impurity partitioning) and perfection (dislocations and other lattice defects) in single crystals, we can deduce how and by what mechanism the crystal grew and experienced fluctuation in growth parameters through its growth and post-growth history under unconstrained condition. The information is useful not only in finding appropriate way to growing highly perfect and homogeneous single crystals, but also in deciphering letters sent from the depth of the Earth and the Space. It is also useful in discriminating synthetic from natural gemstones. In this chapter, available methods to obtain molecular information are briefly

5.1	Background	134

5.5	Internal Morphology	146
5.6	Perfection of Single Crystals	152
	References	156

summarized, and actual examples to demonstrate the importance of this type of investigations are selected from both natural minerals (diamond, quartz, hematite, corundum, beryl, phlogopite) and synthetic crystals (SiC, diamond, corundum, beryl).

The morphology, perfection, and homogeneity of single crystals and the textures of polycrystalline aggregates vary depending on their growth conditions and are determined by the atomic process and mechanism of crystal growth, which occurs exclusively at the solid-liquid interface. Understanding how crystals grow at the atomic level is the key to understanding how and why single crystals can have various morphologies and degrees of perfection and homogeneity depending on their growth parameters. This will provide essential information for both the fundamentals and the applications of crystal growth. Based on such understanding, we may obtain useful hints to develop appropriate methods for the growth of single crystals with desired perfection and homogeneity. We may also decipher how and under what conditions crystals of terrestrial and planetary minerals, as well as biominerals, grew and what sort of changes they experienced, based on this understanding. The purpose of this chapter is to summarize presently available understanding of why and how the morphol-

ogy, perfection, and homogeneity of single crystals are determined by their growth process. Since crystals growing in dilute multicomponent solution phases or by the chemical vapor transport (CVT) process show much wider variations in these properties than crystals grown in simpler monocomponent melt phase or by the physical vapor transport (PVT) process, actual examples to demonstrate how morphology, perfection, and homogeneity are controlled during growth processes will be selected from the former crystals, grown under unconstrained conditions, such as natural minerals or synthetic crystals whose growth process cannot be traced in situ.

Growth of crystals takes place uniquely at the solid-liquid interface, and the growth mechanism and growth rate versus driving force relations are determined by the structure of this interface, i. e., whether the interface is smooth or rough, and the roughening transition of smooth interfaces depending on the growth parameters. The process and mechanism of crystal growth at

the atomic level are recorded in the surface microtopography of crystal faces. A surface microtopograph of as-grown faces provides information on the atomic processes of crystal growth. By examining this surface, the external morphology of crystals, i.e., the evolution of the bulk morphology of three-dimensional (3-D) crystals from polyhedral, to hopper, to dendritic forms (habitus and tracht) is determined. Also the origin of malformed morphologies of two-dimensional (2-D, epitaxial) and one-dimensional (1-D, whisker) crystals may be understood. Similarly, through growth

process, various internal morphologies such as growth sectors, intrasectorial sectors, growth banding, imperfections (dislocation distribution), and inhomogeneities (element partitioning) can be determined and recorded as internal morphologies in nearly perfect single crystals. By applying sensitive methods to visualize or measure perfection and heterogeneity in single crystals, we may obtain useful information about how a single crystal grows and how its perfection and homogeneity are determined, and the whole growth history may be analyzed based on this information.

5.1 Background

Single crystals of various compounds have been synthesized in various sizes and forms, ranging from millimeter to meter scale in size, and from 3-D bulk, to 2-D thin film, to 1-D whisker in form, to meet corresponding requirements for scientific or industrial purposes. Bulk single crystals of large sizes are synthesized to obtain slices for semiconductor, optoelectronic, magnetic, telecommunication, and sensor devices, or to obtain synthetic gemstones, whereas millimeter size is sufficient for protein crystals for crystal structure analysis. Recent interest in nanotechnology has expanded the size ranges down to nanometer scale, and form to include hierarchical structures.

Since the size, form, perfection, and homogeneity of single crystals are essential factors for their use, various growth techniques have been designed and developed to obtain single crystals of appropriate size yet with desired form, perfection, and homogeneity, including:

1. Selection of appropriate ambient phase (melt, solution, vapor), i.e., selection of condensed or diluted phase, and of suitable solvent components
2. Homogenization of ambient phase by internal stirring or external rotation, or by applying magnetic or low gravity field
3. Using seed or substrate crystal to suppress unnecessary nucleation and control crystallographic orientation
4. Controlling temperature or concentration to realize a steady-state yet high rate of growth
5. Minimizing dislocation generation by selection and treatment of seed or by changing boule shapes during growth, or by other techniques.

In the synthesis of Si single-crystal boules larger than a few tens of centimeters across and longer

than 1 m, techniques to control dislocation densities have been successfully realized to obtain so-called dislocation-free Si crystals. In the syntheses of compound semiconductors, ammonium dihydrogen phosphate $\text{NH}_4\text{H}_2\text{PO}_4$ (ADP), potassium dihydrogen phosphate KH_2PO_4 (KDP) or quartz single crystals, further efforts are still required to reach the same level as in Si crystals for the realization of *dislocation-free* crystals, although large-scale mass-production techniques and techniques to grow meter-size crystals are already well established. Polymer and protein single crystals are still in the state of characterizing dislocations and understanding how they are generated, whereas in nanometer-sized ultrafine crystals, control of morphology and hierarchical structure is the present main interest.

Compared with previous efforts to understand the nature and origin of crystals and control dislocations, less effort has been invested in understanding and controlling the chemical homogeneity of single crystals, i.e., element partitioning in relation to growth kinetics. The Burton–Prim–Slichter (BPS) formula [5.1] describing the relation between element partitioning and growth kinetics, proposed half a century ago, still plays an important role in this respect. This problem is still fresh in terms of the synthesis of perfectly homogeneous single crystals in solution systems more complicated than for the simpler melt growth of Si crystal.

In contrast to synthetic crystals, single crystals of natural minerals grow under given geological environments and unconstrained conditions. Their growth and postgrowth histories vary depending on geological environments and processes. In the growth and postgrowth histories, conditions may fluctuate or abruptly

change, which modifies the morphology, perfection, and homogeneity of the crystal. Such variations and fluctuations are recorded within nearly perfect single crystals in the form of macromorphology (external forms), micromorphology (surface microtopography of crystal faces), and internal morphology (growth sectors, intrasectorial sectors, growth banding, the spatial distribution of lattice defects, and associated element partitioning). The morphological features, perfection, and homogeneity of single crystals of natural minerals, both terrestrial and extraterrestrial in origin, therefore provide the key to decipher how mineral crystals grew [5.2,3], as their perfection and homogeneity were determined during growth in ambient phases with complicated compositions under unconstrained conditions, provided that these can be visualized and characterized at the nm to μm scale. We have various sophisticated methods to characterize perfection and homogeneity within a nearly perfect single crystal. Nanometer-level information relating to growth mechanisms can be secured through surface microtopographic observations of crystal faces by means of various sensitive optical microscopy and interferometry techniques such as phase-contrast microscopy (PCM), phase-shifting microscopy (PSM), differential interference contrast microscopy (DICM), laser-beam scanning (LBS) microscopy, phase-shifting interferometry (PSI), and multiple-beam interferometry (MBI), as well as atomic force microscopy (AFM) and scanning tunneling microscopy (STM) [5.3, 4]. X-ray topography (XRT) is a powerful method to visualize the three-dimensional distribution of line and planar lattice defects, and micro-area x-ray fluorescence (MXRF), cathode-ray luminescence (CL), and laser-beam tomography (LBT) are useful characterization techniques to visualize the distribution of point defects and impurities in nearly perfect single crystals [5.3].

Information obtained through characterization of single crystals grown under unconstrained conditions provides useful background knowledge for the design of new techniques to control the perfection and homogeneity of synthetic single crystals, and also to distinguishing natural from synthetic crystals, since these crystals provide the full range of information relating to how imperfections and heterogeneities are generated and induced in single crystals during growth and their postgrowth history. To point out just one example demonstrating the importance of knowledge about the growth process of natural minerals in developing a new method for industrial purposes, we may men-

tion the concept of *epitaxy*. Growth of guest phase on host phase with a definite crystallographic relation is known from many examples of natural minerals, and later this relation was used to grow thin films of single crystals to prepare electronic devices, by either vapor- or liquid-phase growth.

Since the perfection and homogeneity of single crystals are both related to the mechanism, kinetics, and process of growth, which are reflected in the morphological features of the crystals, it is essential to understand how and why morphological variations occur on growing crystals. To this end, single crystals grown from solution phase and under unconstrained conditions provide more useful information than those formed in simpler melt or vapor phases (physical vapor transport, PVT, or physical vapor deposition, PVD) under constrained conditions. It is the purpose of this chapter to summarize the presently available knowledge on the morphology, perfection, and homogeneity of single crystals of mainly natural minerals, but also synthetic crystals whose growth process cannot be traced in situ, such as synthetic crystals grown in high-temperature solution, high-pressure high-temperature solution, hydrothermal solution, and by chemical vapor transport (CVT) method. We pay most attention to single crystals grown from the solution phase and by CVT method, since they represent crystals grown in multi-component and more complicated systems, and show all phenomena relating to crystal growth. Although large single crystals can be synthesized by methods using condensed melt phase, e.g., Czochralski, Verneuil, and Bridgman–Stockbarger methods, the solid–liquid interfaces in these synthesis are generally rougher than in the case of diluted solution or vapor growth, and thus morphological changes are less enhanced. In diluted solution and vapor growth, the solid–liquid interface is generally smoother than in condensed melt growth, leading to more variable morphological variations [5.3]. As compared with melt and PVT growth, solute–solvent interaction is involved in solution and CVT growth, thus providing additional information. We therefore purposely select crystals grown from solution and CVT, both natural and synthetic, to investigate the associated problems, although they are more complicated than those grown from pure melt or by PVT. Most crystal growth in nature, including crystallization in magma, pegmatite, and hydrothermal veins, as well as in regional and contact metamorphic rocks, can be regarded as solution or CVT growth [5.2, 3, 5]. There is no pure melt or PVT growth in natural crystallization.

5.2 Smooth and Rough Interfaces: Growth Mechanism and Morphology

Crystal growth takes place uniquely at solid–liquid interfaces. Depending on the atomic structure of the solid–liquid interface, the growth mechanisms and normal growth rate R versus driving force $\Delta\mu/(k_B T)$ relations are different, resulting in different morphology. The larger the R , the earlier the face disappears from the growing crystal. To nucleate and grow a crystal, a driving force must overcome the respective energy barrier. Throughout this chapter, the driving force is expressed in a general form by the chemical potential difference between solid and liquid phases $\Delta\mu/(k_B T)$. The phase with the larger chemical potential will have to diminish while the phase with the smaller chemical potential will grow, until equilibrium is reached and $\Delta\mu = 0$. If we consider the growth of a solid phase from a vapor or solution at temperature T_B and solute concentration C , the chemical potential difference is obtained by $\Delta\mu = k_B T_B \ln S$, where $S = C/C_\infty$ is the supersaturation ratio defined with respect to the equilibrium concentration C_∞ .

It has been well established [5.3] that:

1. An adhesive-type growth mechanism operates on an atomically rough interface, whereas either two-dimensional nucleation growth (2-DNG) or a spiral growth mechanism operates on an atomically smooth interface.
2. Relations between normal growth rates R and driving forces $\Delta\mu/(k_B T)$ are different depending on the growth mechanism.
3. A smooth interface may transform to a rough interface with increasing growth temperature or driving force.

Taking all these factors into consideration, we may expect that the morphology of a single crystal will change with increasing driving force $\Delta\mu/(k_B T)$ (which can be correlated to the supersaturation σ or supercooling ΔT) from polyhedral, via hopper (skeletal), to dendritic forms (all being morphologies of single crystals). On further increases of the driving force, semispherulite to spherulite or more complicated morphologies of polycrystalline aggregate are expected to appear, as the nucleation rate increases. Two critical driving force conditions, $\Delta\mu/(k_B T^*)$ and $\Delta\mu/(k_B T^{**})$ are present with increasing driving force, judging from the growth rate versus driving force relations expected for different growth mechanisms [5.2,3,5]. Under driving force conditions above $\Delta\mu/(k_B T^{**})$, the interface is expected to be rough, while below this the interface will be smooth. Above $\Delta\mu/(k_B T^{**})$, the interface is rough and the principal growth mechanism is of adhesive type. The morphological stability of such an interface is lower, and more easily violated on rough than smooth interfaces. Morphological instability of a rough interface leads to cellular growth and the appearance of dendritic morphology. Below $\Delta\mu/(k_B T^{**})$, the interface is smooth and the principal growth mechanism is either 2DNG or spiral growth. Due to the presence of the Berg effect [5.6], i.e., a higher driving force along the edges or corners of a face on a polyhedral crystal than at the center of the face, growth layers originate near the edges and corners and advance inwards to the center of the face. Therefore, a crystal takes a hopper or skeletal form under the driving force condition between $\Delta\mu/(k_B T^*)$ and $\Delta\mu/(k_B T^{**})$. Below $\Delta\mu/(k_B T^*)$, spiral growth layers originating from the center of a face advance toward its periphery, leading to the formation of a polyhedral crystal bounded by flat low-index faces. In Fig. 5.1, the morphological evolution of a crystal is indicated schematically in re-

Fig. 5.1 Schematic illustration of the morphological evolution of a crystal on a normal growth rate R versus driving force $\Delta\mu/(k_B T)$ diagram. Curve (a) corresponds to spiral growth mechanism, curve (b) to 2DNG, and curve (c) to adhesive-type growth mechanism. Two critical driving forces $\Delta\mu/(k_B T^*)$ and $\Delta\mu/(k_B T^{**})$ are shown for one crystallographic face, and the regions where polyhedral, skeletal, dendritic, spherulitic, and fractal morphologies are expected are indicated (after [5.3,5])

lation to the driving force, interface roughness, growth mechanisms, and normal growth rate R versus driving force $\Delta\mu/(k_B T)$ relations [5.2, 3, 5]. The positions of $\Delta\mu/(k_B T^*)$ and $\Delta\mu/(k_B T^{**})$ on the driving force axis are different depending on the crystal face. The smoother the interface, the higher these values.

The morphological evolution from polyhedral, via hopper, to dendritic form with increasing driving force is expected theoretically and observed experimentally for many crystals grown in vapor and solution phases, such as snow crystals grown in vapor phase and silicate crystals formed in magmatic solution at elevated temperature. The reader may refer to [5.2, 3, 5] for details.

Under a driving force lower than the critical value $\Delta\mu/(k_B T^*)$ the morphology is polyhedral bounded by low-index crystal faces with slow normal growth rates. If growth continues for enough time and the crystal reaches equilibrium with the surrounding phase under a given thermodynamic condition and no further change is expected to occur, the crystal will be bounded only by the faces with the slowest, or second and third slowest, normal growth rates. The crystal morphology expected in the equilibrium state can be regarded as the *equilibrium form* under the given thermodynamic conditions. The sum of the surface free energy times the surface area will be minimum owing to the thermodynamic requirement of anisotropic material. In contrast, the equilibrium form of an amorphous material, such as a liquid, is a sphere. The equilibrium form was theoretically analyzed by Curie [5.7], Wulff [5.8], Gibbs [5.9], and more recently by Kern [5.10]. Through these analyses, a few important concepts relating to growth and morphology of crystals emerged, as summarized below:

1. The normal growth rates R of crystal faces are proportional to the surface energy γ . The smaller the surface energy, the slower the normal growth rate. This is strictly speaking valid only for molecular crystals [5.11, 12], but may be qualitatively applicable when the relative morphological importance of different faces is compared.
2. A polar diagram of *raspberry* shape, called a Wulff plot, can be drawn by connecting plots proportional to the surface energies.
3. The equilibrium form is obtained by connecting inscribed lines drawn on the cusps of the Wulff plot.
4. The equilibrium form corresponds to the form with minimum total surface free energy under a given thermodynamic condition, and not the growth forms, neither structure form.

In cubic crystals with equal axial lengths, polyhedral crystal will be bounded by only one crystallographically equivalent faces with the minimum surface energy. In anisotropic crystals, the equilibrium form of a polyhedral crystal is bounded by two or more crystallographic faces with the smallest, and second and third smallest, surface energies. Depending on the crystallographic system and axial relations, different characteristic growth forms appear, generally called the crystal habit, or more precisely habitus. Habitus is the characteristic form exhibited by a crystal species grown in an isotropic environment. Crystals belonging to the cubic system, or those with other systems but having nearly equal axial lengths, take equant habit. Crystals belonging to lower-symmetry systems, or with markedly different axial lengths, exhibit prismatic or platy habit. Crystals with much shorter axial length in the c -axis than the a - and b -axes take prismatic habit, whereas those with longer axial length in the c -axis take platy habit perpendicular to the c -axis. The expected polyhedral form of a given crystal is thus correlated to the symmetry elements involved in the unit cell, the crystal system, the crystal group, the space group or the chemical bonding in the crystal structure. Such morphology deduced from crystal structure alone can be called *structural form*, and be deduced theoretically based on types and symmetry elements, or by analyzing strong bonds in the structure, entirely neglecting the effect of thermodynamic or kinetic parameters. Examples of such analyses are the oldest Bravais–Friedel (B–F) law [5.13], an analysis based on leticular density or leticular spacing of unit-cell geometry, and Donnay–Harker’s (D–H) extension of the B–F law [5.14], in which symmetry elements involved in 230 space groups are taken into consideration. In these analyses, the order of morphological importance of the crystal faces can be deduced by calculating leticular densities or spacing. The higher the leticular density or the wider the leticular spacing, the higher the order of morphological importance. The order of morphological importance may be evaluated based on statistical observations of the frequency of occurrence and relative development of faces, or by comparing surface microtopographic characteristics of faces on a crystal. However, B–F or D–H analyses do not predict whether the face belongs to a smooth interface or rough interface, or the surface microtopography of crystal faces.

On the other hand, Hartman–Perdok’s periodic bond chain (PBC) theory [5.15–17] considers strong bond chains involved in crystal faces, and the connected net model of Bennema and van der Eerden [5.11] also

considers chemical bonding in the structure. These analyses can correlate the result to interface roughness, i. e., whether a face is rough or smooth, and quantitatively evaluate surface energy terms by calculating the attachment energies of slices E_{att} [5.12]. In the H–P theory, crystal faces containing more than two PBCs are called flat (F) faces, which correspond to smooth interfaces, whereas those containing no PBCs are called kinked (K) faces corresponding to rough interfaces. Stepped (S) faces containing only one PBC correspond to an intermediate between F and K faces, and appear by piling up of edges of growth layers developing on adjacent F faces. No growth layers will develop on S or K faces. When a crystal has more than one F face, their order of morphological importance is determined by the strength of the PBCs involved in the respective faces, and follows the order of attachment energies [5.11, 12]. These analyses can also predict the morphology of growth spirals on different faces.

All these models predict the morphologies of polyhedral crystals, based purely on the structural factor, entirely neglected the effect of external factors. These morphologies are thus considered the *structural form*. They can be different from actually observed morphology, i. e., *growth forms*, but can be used as a criterion for analyzing growth forms or the origin of their variation.

The morphology of polyhedral crystals is determined by the internal structural factor and external factors, and thus is not necessarily the same as the equilibrium or structural form. We have to take the following into consideration as possible factors affecting interface structures: ambient phases (condensed or diluted phases, involving solute–solvent interaction or not, and the strength of solute–solvent interaction), growth conditions (temperature, pressure, supercooling, supersaturation, diffusion, and convection), solvent and impurity components which modify surface or edge energy terms, and dislocations. Depending on how and under what conditions and by what processes polyhedral crystals are formed, different faces appear or disappear. Even crystallographically equivalent faces may develop with different sizes. Such morphology is called *growth forms* (plural), and offers information about how and under what conditions or conditional changes the crystal grew. Growth forms of polyhedral crystals may be bounded by more faces than the equilibrium or structural form, or by crystallographically equivalent faces of different sizes. In the same crystal habit (habitus) category, various forms may appear through different combinations and development

of crystal faces. *Tracht* is a term that denotes variation within the same category of habitus, due to the combination and development of different faces. Malformation of polyhedral forms from the ideal habitus occurs for various reasons, such as anisotropy in the crystal itself (spatial distribution and density of active dislocations for growth) or in the ambient phase (solution flow, convection, and the presence or absence of obstacles such as substrate surface or inclusions), and the presence or absence of seed. Information obtainable through variation in habitus and *tracht* tells us how the crystal grew and how the condition fluctuated throughout its growth history. Such information is very useful in analyzing conditional changes in the growth history of crystals whose growth process cannot be traced in situ (natural minerals, or crystals synthesized in enclosed systems), and to design appropriate methods to control the growth parameters to obtain single crystals of desired perfection and homogeneity.

It is to be noted that even ultrafine crystals of nanometer size show polyhedral morphology bounded by flat crystallographic faces. Ultrafine particles of not only metals but also various compounds show polyhedral morphology; for examples see [5.18] and many other papers. Only crystals smaller than 1 nm show forms without crystal faces.

Another morphology to be mentioned is whiskers. Depending on the anisotropy involved in growth sites, extremely anisotropic morphology appears. Such crystals are called whiskers, and have attracted both scientific and application interests, due to curiosity about the origin of their unusual morphology and their much higher perfection than 3-D bulk crystals. Most whiskers are straight, but topological whiskers, such as helical, coil, ribbon, and rope forms, are also known. A variety of mechanisms to account for whisker growth have been proposed, but only a few models have been established. The vapor–liquid–solid (VLS) mechanism [5.19] put forward as a possible mechanism for Si whisker formation is such a case. Detailed discussion on the mechanism of whisker formation will be given in Sect. 5.4. There are other well-established mechanism for whisker formations, and a discussion of possible mechanism is given in Sect. 5.4 and can also be found in [5.3].

We shall analyze in more detail in Sect. 5.4 possible reasons for the formation of various growth forms. However, before dealing with the macromorphology of crystals, it is necessary to understand at the atomic level how crystal growth proceeds. This is recorded in the form of the surface microtopography of crystal faces.

5.3 Surface Microtopography

Since growth (and dissolution) takes place exclusively at the solid–liquid interface, growth (and dissolution) process are recorded in the form of the surface microtopography of the crystal faces. Well-developed as-grown low-index faces corresponding to F faces show surface microtopography characterized by the development of step patterns resembling contour lines of a geographic map. They consist of flat terraces and sharp steps, with elemental height of nanometer order originating from screw dislocations, as well as bunched macrosteps with thicker step height. On terraced portion, which is usually atomically flat, islandlike layer formed by two-dimensional nucleation may occasionally be seen, where condition is changed to terminate the growth, leading to shoot up of the driving force. Islandlike layer formed by 2DNG mechanism is not commonly seen on inorganic crystal grown freely, but is more frequently encountered on protein crystals, probably due to the higher driving force conditions necessary to grow pro-

tein crystals and the larger size of the growth units involved in their growth. At least based on the author's experience of surface microtopographic observations of a wide variety of inorganic crystals, features conclusively demonstrating 2DNG have never been observed. The author is always careful to draw a conclusion about 2DNG based on islandlike patterns.

The surface microtopography of S faces is characterized by straight striations parallel to edges with adjacent F faces, whereas those of rough K faces show rugged, hummocky, rough surfaces. On both S and K faces, neither spiral step pattern nor two-dimensional island are observed. Surface microtopographs characteristic of smooth F, intermediate S, and rough K faces are illustrated schematically in Fig. 5.2a–c, respectively.

When F faces receive dissolution (etching), various etch figures appear, which include point-bottomed etch pits (P-type) formed at outcrops of dislocations, flat-bottomed etch pits (F-type) formed at outcrops of

Fig. 5.2a–g Schematic illustrations of surface microtopographs expected to be observed on F (a), S (b), and K faces (c) formed by growth, and P-type (d), F-type (e) etch pits and etch hillock (f), and concave steps (g) due to two-dimensional recession of smooth growth steps on an F face. Microtopographs (a–c) are due to growth, whereas microtopographs (d–g) are due to dissolution (etching). Microtopographs (d–f) are illustrated by oblique illumination, whereas in (g), higher sides of steps are *shadowed*

point defects or impurity atoms, etch hillocks formed around obstacles such as dislocations decorated by impurities, and concave and rugged steps formed by two-dimensional recession of smooth growth steps. These are illustrated schematically in Fig. 5.2d–g.

If sophisticated methods to visualize and measure nanoscale steps are used, a spiral step pattern originating from isolated screw dislocations with elemental Burgers vector, and constant step separation can be seen on well-developed crystal faces. An elemental spiral originating from an independent screw dislocation has a profile consisting of atomically flat terraces and steep steps with height equal to the component of the Burgers vector perpendicular to the face, and with constant step separation. Depending on the growth conditions and ambient phases, the ratio of step separation λ to step height h varies. On crystals grown in very diluted vapor phase, the ratio is on the order of 1×10^3 – 1×10^5 , whereas on the same face of the same crystal grown

in less diluted solution phase it is on the order of 1×10^2 – 1×10^3 [5.20]. It is to be noted that the profile of an elemental growth spiral is such that, after walking on an extremely flat plateau for 1–10 km, one meets a sharp cliff 1 m in height. Phase-contrast (PCM), interference contrast (DICM), and phase shifting (PSM) microscopes can reveal such spiral steps with nanoscale height, and multiple-beam (MBI) and phase-shifting (PSI) interferometry can measure the height of such thin steps. The step height of an elemental spiral is equal to the unit cell height, or its fraction in the direction perpendicular to the face. The step separation of an elemental spiral corresponds to twice the radius of the critical two-dimensional nucleus under the given conditions. The step separation λ of an ideal elemental spiral is equal to $19r^*$, where r^* is the radius of the critical two-dimensional nucleus. r^* is determined by the edge free energy γ and the driving force $\Delta\mu = k_B T \ln S$ according to

$$r^* = 2\gamma \frac{\rho}{mk_B T \ln S}, \quad (5.1)$$

where m is the mass of one molecule and ρ is the density of the nucleus volume.

With increasing $\Delta\mu/(k_B T)$, λ becomes narrower when crystals grow in the same ambient phase. γ is modified by solute–solvent interaction and impurities adsorbed on the steps.

When the step separation is wider than the resolution limit of the microscopy adopted, the ideal spiral pattern is discernible. With increasing driving force, the step separation becomes narrower than this resolution and individual steps become impossible to resolve. Such growth spirals will appear in the form of growth hillocks with pointed summit, bounded by vicinal faces. If observation methods with higher horizontal resolution and equally high vertical resolution, such as atomic force microscopy (AFM), scanning tunneling microscopy (STM), or laser beam scanning microscope (LBSM) are applied, spiral steps may become discernible on the summit of such growth hillocks.

Growth spirals with elemental step heights take circular or polygonal form depending on the roughness of the spiral steps. A circular spiral appears when the step is rough, whereas a polygonal form appears when the step is smooth. So the same concept applied to the roughening transition of a smooth interface is applicable in this case too. The circular form appears under higher driving force conditions, whereas the polygonal form is seen when the driving force is below the critical value for the two-dimensional roughening tran-

Fig. 5.3a–c Variation in the roundness of steps of growth spirals observed on different crystal faces of a hydrothermally grown synthetic beryl crystal. Regular hexagonal spirals are seen on the morphologically most important (0001) face (a), slightly rounded rectangular spirals are observed on the second important (1010) face (b), and rounded growth hillocks are observed on the far less important (2131) face (c). Growth features become more rounded with decreasing morphological importance

Fig. 5.4a–c Symmetry of polygonal growth spirals observed on crystals of different crystal systems: (a) hexagonal spiral observed on (0001) face of a hexagonal system, SiC, (b) triangular spiral observed on (0001) face of a trigonal system, hematite and (c) five-sided spiral containing only one mirror symmetry plane observed on (001) face of a monoclinic crystal, phlogopite. In (b), the crystal receives weak etching, forming rugged steps due to two-dimensional recession (dissolution) of smooth growth steps. In (c) spiral steps with height of 1 nm are decorated by selective nucleation of foreign crystals along the spiral steps

sition. The critical points for the roughening transition to take place may differ on the same crystal face depending on the growth parameters as well as on different faces on the crystal grown under the same conditions. On the same faces of crystals grown under different conditions, circular or polygonal spirals may be seen depending on the growth conditions. More polygonal spirals appear on crystals grown under lower driving force conditions than those grown under higher driving force conditions. Polygonal spirals may be observed on the morphologically most important face, whereas circular ones are seen on morphologically less important faces on the same crystal grown under the same conditions. Representative examples to demonstrate such variation is shown in Fig. 5.3. When spirals take the polygonal form, their symmetry follows that of the face,

since the steps are determined by PBCs involved in the face. Figure 5.4 shows representative examples of various morphologies of growth spirals observed on the faces of crystals belonging to different crystal systems.

Growth spirals with elemental step height bunch together to form thicker macrosteps while advancing

Fig. 5.5 An example of a step pattern observable on a whole face. More perturbed, bunched macrosteps appear closer to the edges of the face at the *bottom right*. All perturbed macrosteps seen at the lower right are bunched macrosteps originating from elemental spiral centers indicated by the *arrows*. Also note the wider step separation along the upper edges, which is considered as due to a higher driving force along the edge than at the center of the face, i. e., the Berg effect. Hematite (0001) ►

Fig. 5.6a–d Surface microtopographs of prism (a,b) and rhombohedral (c,d) faces of natural (a,c) and synthetic (b,d) quartz crystals. Arrows in (b) indicate spiral centers

laterally, due to either impurity adsorption along the step or fluctuations in the driving force over the surface. Since the advancing rate of a bunched macrostep is slower than that of elemental steps, the step pattern is perturbed more as it advances laterally. Since the driving force near the edges and corners of a crystal face is higher than at the center of a face due to the Berg effect [5.6], the step separation becomes narrower and the step pattern becomes more perturbed when advancing close to edges. Figure 5.5 shows such an example.

On real crystals, it is exceptional for a whole crystal face to be entirely covered by one spiral step pattern, with a constant step separation, originating from an outcrop of an independent screw dislocation. Several or a large number of growth spirals appear on one face, originating from several dislocations. So, step patterns observable on the same crystallographic face can differ from crystal to crystal, or among crystallo-

graphically equivalent faces, even if the crystal grew in similar ambient phases under similar growth conditions. However, overall surface microtopographs show characteristics corresponding to the crystal growth environment and conditions. The same hematite crystals occurring at different localities, but formed in similar ambient phases, i. e., natural CVT due to postvolcanic action, show surface microtopographic characteristics according to which different localities can be identified. Prism and rhombohedral faces of natural and synthetic quartz crystals show markedly different surface microtopographies according to which natural and synthetic crystals can be easily discriminated, even if both show the same hexagonal prismatic habit. In Fig. 5.6, surface microtopographs of prism (Fig. 5.6a,b) and rhombohedral (Fig. 5.6c,d) faces of natural (Fig. 5.6a,c) and synthetic (Fig. 5.6b,d) quartz are compared. The marked differences between natural and synthetic quartz crystals are due to the differences in growth rates (natural crystals grew slower under lower driving force conditions than synthetic crystals) and solution chemistry (natural quartz grows in neutral hydrothermal solution, whereas synthetic quartz in alkaline solution).

5.4 Growth Forms of Polyhedral Crystals

Polyhedral crystals bounded by flat crystallographic faces are formed by the spiral growth mechanism under conditions lower than $\Delta\mu/(k_B T^*)$. If a crystal grows in an isotropic environment, i. e., in an ambient phase with a concentric diffusion gradient toward the growing crystal, the growth form is determined simply by the relative normal growth rates of the faces present on the crystal surface. The morphology eventually reaches a form corresponding to a structural or equilibrium form. Crystallographically equivalent faces develop equally in size. If additional factors that may induce anisotropy in the mass transfer in the ambient phase or in the distribution of dislocation outcrops active as growth centers are involved, polyhedral growth forms deviate or are malformed from their ideal form. Even crystallographically equivalent faces will develop differently. As possible factors to induce such anisotropy, we may mention the following:

1. Convection or directional flow in the ambient phase, which induces anisotropy in mass transfer. This may result in not only modification of growth rates but also in the distribution of inclusions from which dislocations are newly generated.
2. The presence of seed or substrate surface. Seed modifies the growth form, and the surface of seed or substrate affects normal growth rates by newly generating dislocations on the interface.
3. The presence of reentrant corners or concentration of dislocations in twin junctions due to twinning. These provide sites for preferential growth.
4. Anisotropic distribution of active growth centers, i. e., outcrops of screw-type dislocations, for various reasons, such as new generation of dislocations from inclusions.
5. Impurity elements selectively adsorbed along growth steps or foreign compounds that selectively cover the growing surface due to epitaxial relation, or selective adsorption that suppresses the normal growth rate.

Since an ideally isotropic environment is not expected in real systems, actually observed polyhedral crystals show various forms which deviate or are malformed from ideally expected forms, i. e., the structural or equilibrium form. Even a simple octahedral crystal bounded by crystallographically equivalent {111} faces may only take polyhedral forms such as tetrahe-

dron, triangular or hexagonal plate, or even elongated rodlike form, due to anisotropic development of crystallographically equivalent faces. In Fig. 5.7, various polyhedral forms appearing due to anisotropic development of crystallographically equivalent {111} faces are shown. We shall in the following first analyze growth forms expected in an isotropic environment, and then proceed to the analysis of possible reasons for such deviations.

The normal growth rate R of a face growing by the spiral growth mechanism is determined by the height h , the separation between successive steps λ , and the advancing rate v of the spiral step $R = hv/\lambda$. Since h corresponds to the Burgers vector of dislocation, it is different on different faces. Since λ is equal to $19r_1^*$, and

$$\Delta G(r^*) = 16\pi\gamma^3 \frac{[v]^2}{3\Delta\mu^2}, \quad (5.2)$$

where r^* is the radius of the critical two-dimensional nucleus, γ is the edge free energy of the two-dimensional nucleus, v is the molar volume of the bulk nucleated phase, and $\Delta\mu$ is the chemical potential difference.

Important parameters that affect R , and hence modify the habitus and tracht of polyhedral crystals when

they grow in an isotropic environment, are those that modify the edge free energy and driving force. The following are considered to be the major factors:

1. Driving force, i. e., supercooling or supersaturation.
2. Ambient phase. Crystals of the same species growing from different ambient phases, i. e., those grown from melt, solution or vapor phase, will show different growth forms.
3. Solute–solvent interaction energy, i. e., crystals of the same species grown from solutions with different solvent compositions will show different growth forms.
4. Impurity elements, which modify the edge free energy by adsorbing on spiral growth steps. Foreign compounds which can selectively adsorb or epitaxially grow on particular faces. These may suppress the normal growth rate of rough or less smooth interfaces which grow with high growth rate in the pure system, resulting in marked morphological changes.

Examples demonstrating the effect of these factors are well known and can be found in older works by Wells [5.21] and Buckley [5.22]. Wells demonstrated various examples of variation of growth forms due to effects 1, 2, and 3, and Buckley summarized his observations on effect 4. Observations on the variation of habitus and tracht of mineral crystals in relation to their modes of occurrences and the analysis of their origins may be found in [5.2, 3, 5].

In real systems, polyhedral crystals grow in environmental phases that deviate from the ideal isotropic situation. Mass (or heat) transfer will be anisotropic due to convection or directional solution flow. It was noted as early as the 17th century by Hook [5.23] that alum crystals formed on the bottom of a beaker take hexagonal platy habit bounded by only {111} faces, as compared with the nearly simple octahedral habit of crystals formed on a string immersed in the solution, i. e., those growing in a nearly isotropic environment. Around a crystal growing on the bottom of a beaker, mass transfer to the face adhering to the bottom is strongly suppressed as compared with the faces directly facing to the solution, resulting in remarkable malformation from the ideal octahedral morphology.

Reentrant corners provided by twinning also play a similar role, resulting in triangular or hexagonal platy habit, since preferential growth occurs at a reentrant corner due either to the geometry or the concentration of dislocations in the twin junction plane.

Fig. 5.7a–d A simple octahedral crystal bounded by {111} only (a) may take various malformed forms: tetrahedral (b), triangular platy (c) or elongated rodlike (d) due to anisotropy in either environmental factors or in the crystal itself

Convection or directional flow of solution is universally involved in mineral formation in hydrothermal veins in nature and in hydrothermal synthesis in the laboratory. When crystals grow in an impure system, precipitation and incorporation of solid grains of foreign minerals or mother liquid phase as inclusions in the growing crystal is also anisotropic, which will enhance growth rate anisotropy. Since such inclusions act as sites generating new dislocations, the density of outcropping dislocations on crystallographically equivalent faces become different, resulting in different growth rates. Depending on the conditions of solution flow, laminar or turbulent, the rate of mass transfer and the precipitation of foreign particles may be different. In turbulent flow, the growth rate is enhanced and more inclusions are included on the rear side of the solution flow than on the front side. Variation of normal growth rates or the precipitation and inclusion of foreign particles are recorded in the forms and sizes of growth sectors, the width of growth banding, and the distribution of centers of dislocation generation detectable in single crystals. Such internal morphology of single crystals offers important information for the analysis of growth history and conditional variations during growth. These will be described in more detail in Sect. 5.5.

When aiming to synthesize large single crystals of high perfection at high growth rate in the laboratory, seed crystals are generally used to suppress unnecessary spontaneous nucleation. Other techniques, such as the application of an alternating temperature to dissolve unnecessary nuclei, agitation and stirring of the solution, rotation of the crucible, application of a magnetic field, and growth under microgravity conditions, are applied to homogenize the ambient phase.

In preparing the seed, it is common to adopt a crystallographic orientation bounded by rough or less smooth interfaces to secure a higher growth rate and obtain forms appropriate for industrial use. The crystallographic orientations and surfaces of seed are generally chosen as different from those observed on freely grown forms. *Y*-bar seed for the hydrothermal synthesis of quartz and a seed plate parallel to $[21\bar{3}1]$, often used in the hydrothermal synthesis of emerald, are such examples. The seed surface is often treated by chemical etching before the onset of new growth. This results in markedly different as-grown morphology of syn-

Fig. 5.8a,b Natural quartz crystal grown without seed (a) and synthetic crystals grown on seed plate (Y-bar) (b). The *c*-axes are set vertically in both photographs ►

thetic crystals from those grown freely. Seed surfaces are usually those not seen on freely grown crystals, and belong to the category of rough interfaces. They often develop to a large size on synthetic crystal. On natural quartz crystals, $\{0001\}$ faces never appear unless a special effect is involved, whereas on synthetic quartz crystals these faces become large. In Fig. 5.8a,b natural and synthetic quartz crystals are compared with the same crystallographic orientation. Natural quartz crystals show hexagonal prismatic form elongated in the c -axis, and bounded by prism $\{10\bar{1}0\}$, two types of rhombohedral $\{10\bar{1}1\}$ and $\{01\bar{1}1\}$ faces, whereas synthetic crystals show prismatic form elongated along the Y -axis and perpendicular to the c -axis and bounded by basal $\{0001\}$, prism $\{10\bar{1}0\}$, $\{11\bar{2}0\}$, rhombohedral $\{10\bar{1}1\}$, $\{01\bar{1}1\}$ and trigonal pyramid $\{11\bar{2}2\}$ faces. $\{0001\}$, $\{11\bar{2}0\}$, and $\{11\bar{2}2\}$ faces are not commonly observed on freely grown quartz crystals. The difference is simply because the growth of synthetic quartz is forced to terminate before the crystal attains its final form. If growth proceeds further, synthetic quartz crystals will eventually show similar hexagonal prismatic form to natural quartz crystals. Spontaneously nucleated quartz crystals without seeds on the holder in the same autoclave take trigonal or hexagonal prismatic form, similar to natural crystals, except with more exaggerated trigonal symmetry than natural quartz.

Although not common, we may occasionally identify seed crystals in single crystals of natural minerals as well. The seed is formed elsewhere in a different geological environment and later incorporated into a new environment where further growth takes place later. Growth morphology may be different between the seed and the newly grown portion, and dislocations may be newly generated on the seed surface.

In epitaxial growth, the morphology of the guest crystal is different from that of freely grown crystal, since an additional interface energy and steps are introduced between the host crystal surface and the guest crystal due to their epitaxial relation. Epitaxially grown guest crystal usually takes more flattened or elongated forms. Many examples are known among mineral crystals.

5.5 Internal Morphology

Polyhedral crystals are bounded by several crystallographically equivalent or different faces that grow at different normal growth rates R . Crystal faces with smaller R become larger, whereas those with larger

Whiskers are single crystals with highly anisotropic forms. In most cases, they take straight forms, elongated in a certain crystallographic direction and bounded by low-index crystal faces [5.24]. Kinked whiskers are also sometimes observed. Recently, topological whiskers showing twisted, curved, helical, screw, Möbius ring, and other topological forms have been reported [5.25]. To account for the origin of such highly anisotropic morphology of single crystals, we have to assume the presence of a preferential unique growth site, where growth can occur while growth on other sites is suppressed. In the case of the vapor–liquid–solid (VLS) mechanism for Si whiskers [5.19], Si is continually supplied in vapor phase (V), which dissolves in Au particles to form a eutectic Au–Si liquid droplet (L), in which only Si nucleates and grows as whiskers (S). Since growth occurs only at the site of the nucleus, Si crystal grows as a whisker, with a cap of Au–Si eutectic liquid droplet at the tip, and Si is continually supplied from the vapor. In the eutectic solution (L) phase, for thermodynamic reasons (i. e., the lower melting point of the solution than of the pure solute and solvent phases and the phase to nucleate, and that growth in the solution is determined by the composition of the liquid phase), only Si is nucleated in the solution phase, providing a unique growth site, leading to whisker growth. Growth exclusively occurs at the root of whiskers in the eutectic liquid droplets. The VLS mechanism has been well established in many other example systems, including mineral crystals.

Another well-established mechanism for whisker formation was demonstrated in the case of KCl or NaCl crystals [5.26]. When KCl or NaCl aqueous solution in a wineskin is kept in the dark, whiskers of these crystals grow from the outer surface of the wineskin. These whiskers are hollow along their length, indicating that crystal growth occurs as soon as the solution is transported through capillaries in the skin and exposed on the skin surface or the tip of the hollow whisker, since supersaturation sharply increases. Growth uniquely occurs at the tip and, as long as the capillary is present, growth continues, leading to hollow whiskers.

R diminish in size or terminate as growth proceeds. So rough interfaces will disappear very soon from the external form, and only smooth faces will become large. Among smooth interfaces, the morphologically

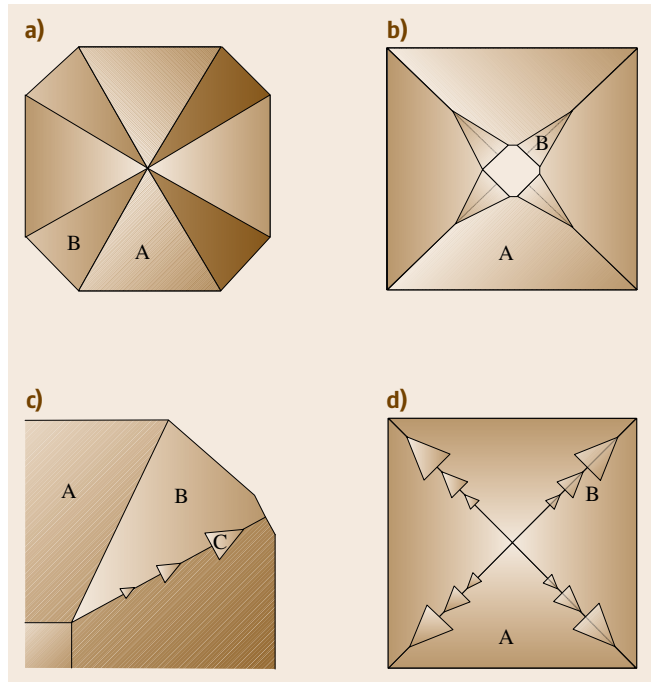

Fig. 5.9a–d Schematic illustration of growth sector boundaries. (a) Straight growth sector boundaries appear when R_A and R_B are constant; convex (b) or concave boundaries (c) appear when R_A or R_B is decreasing. Growth sector boundaries in a crystal bounded by crystallographically equivalent A faces, but with different growth rates are indicated in (d) ►

most important face develops as the largest face while morphologically less important faces develop smaller. Unless some factors suppress or enhance the normal growth rates, the final morphology is the same as that structurally expected. However growth forms are different from ideal forms. Even crystallographically equivalent faces grow at different R when a crystal grows in a real environmental phase in which flow or convection currents or substrate surface are present. The densities of active growth centers (outcrops of dislocations) will not be the same in a real system on growing surfaces of crystallographically equivalent faces, leading to different growth rates. Growth forms of polyhedral crystals may vary as they grow, due to variations and differences in the normal growth rates in different directions as well as changes in the growth conditions.

Through the growth process, pyramidal portions are formed in a single crystal, with their summits at the initiation of the face and the base at their terminations either within the crystal or on the final as-grown surface. These pyramidal portions observable in single crystals are called growth sectors, and can be visualized even in perfectly clean crystals by the naked eye when investigated by applying appropriate methods such as polarization microscopy, CL and laser-beam tomography, x-ray topography, and etching. In the Russian literature, they are called growth pyramids.

Depending on the growth history, various forms of growth sectors appear. If a face grows steadily throughout the whole growth history, the growth sector takes a regular pyramidal form with the summit at the center

Fig. 5.10a–d Schematic illustrating various types of growth sectors. (a) Two faces, A and B, grew at a constant growth rate. (b) The growth rate of sector B increases as growth proceeds and the sector terminates within the crystal. (c) Face C appears due to conditional change, and the corresponding growth sector soon terminates due to the original rapid growth rate. (d) Intermittent growth sectors, indicating repeated changes in growth conditions ►

of the crystal and the base at the final as-grown surface. The boundaries between the adjacent growth sectors detected when a crystal is bisected through the center may be straight, convex or concave, depending on the relative growth rates of the faces, as illustrated schematically in Fig. 5.9. Growth sector boundaries may be detected even between neighboring crystallographically equivalent faces. Since sector boundaries are places where advancing growth steps on the adjacent faces meet, where strain concentrates, they can be detected by appropriate methods. They are often seen by the concentration of mother liquid inclusions.

When one face grows at a much higher growth rate than the neighboring faces, the former growth sector becomes narrower and tapered as growth proceeds and the sector boundaries may terminate within the crystal. This forms a center cross pattern, with tapering growth sectors. If the face appears intermittently, zigzag sector boundaries appear. Figure 5.10a–d shows schematically various types of growth sectors. Clearly, morphologically important faces that behave as smooth interfaces under the growth condition form growth sectors that persist throughout the whole growth history, while morphologically less important faces that behave as less smooth or rough interfaces form tapering or intermittent

growth sectors. In these sectors, the summits and base are just opposite to ordinary observable growth sectors. The base of a pyramid appears first, and the boundaries are tapered as growth proceeds. This indicates that the face appeared when conditions changed to suppress the normal growth rate of the face, which otherwise grows with a higher growth rate. The presence of intermittent growth sectors indicates that an abrupt conditional change took place to suppress the normal growth rate of the face, leading to the appearance of the face, which soon disappears due to the rapid growth rate under the given conditions. Tapered growth sectors may represent either the coexistence of two smooth interfaces with different smoothness, or smooth and rough interfaces. In the case of the coexistence of smooth and rough interfaces, we have to assume an effect of external factors to suppress the normal growth rate of the rough interface. Otherwise, growth sectors corresponding to the rough interface will very quickly disappear from the crystal.

Even if the final morphology is a polyhedron bounded by flat faces, this does not automatically guarantee that the crystal took polyhedral form throughout its growth history, i. e., was formed exclusively under conditions lower than $\Delta\mu/(k_B T^*)$ throughout its whole growth history. They may start as spherulite or den-

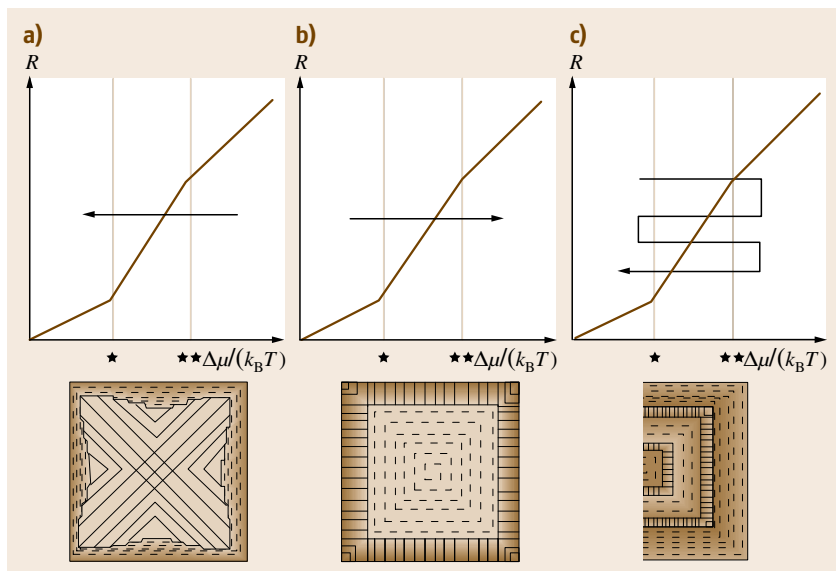

Fig. 5.11a–c Schematic illustrating the internal morphologies of single crystals formed first by dendritic growth followed by 2DNG and spiral growth (a). Fibrous (dendritic) overgrowth on earlier formed polyhedral crystal grown by 2DNG or spiral growth, due to a sharp increase of the driving force by conditional change at the latest stage, is indicated in (b). A case of repeated conditional change is indicated in (c). Corresponding conditional changes are indicated by *arrowed lines* on the respective growth rate versus driving force diagrams shown above

dritic forms under conditions higher than $\Delta\mu/(k_B T^{**})$, and 2DNG or spiral growth may take place later when the driving force drops below $\Delta\mu/(k_B T^*)$. The earlier formed dendritic or spherulitic forms may be found at the center of polyhedral crystals formed through such process, as illustrated schematically in Fig. 5.11. The skeleton and the present size of a polyhedral crystal may have been constructed during the earlier stage of dendrite formation.

So, through the analysis of internal morphology, we may assess how the as-grown morphology of a crystal has changed and which faces persisted and were morphologically important throughout its growth history, and how and why morphologically less important faces appeared or disappeared during the whole growth history of a crystal.

Although less distinct, growth sectors of smaller size can be detected within one growth sector when sensitive observation methods such as polarization microscopy or cathode luminescence tomography are used to detect chemical heterogeneity. Such growth sectors are called intrasectorial growth sectors, or vicinal sectoriality. They appear due to different advancing rates v of spiral growth layers or impurity incorporations between different vicinal faces of a spiral growth hillock developing on an F face. On the surface of an F face growing by spiral growth mechanism, a spiral growth hillock with polygonal form appears, being composed of a few vicinal faces and following the symmetry of the face. The vicinal faces appear by piling up of spiral steps, since the advancing rates of spiral growth layers are different in different directions. Due to the difference in the advancing rate, impurity concentrations can be different between different vicinal faces. This forms vicinal sectoriality or intrasectorial growth sectors. A good example of vicinal sectoriality was reported in [5.27], as revealed by CL on polygonal growth spirals developing on $\{10\bar{1}0\}$ face of synthetic quartz crystal. Brighter CL images corresponding to higher concentration of impurity Al are seen on only two among six vicinal faces forming a polygonal growth spiral. The higher concentration of Al in these vicinal faces results in the appearance and development of $s\{11\bar{2}1\}$, $x\{51\bar{6}1\}$ faces on natural quartz crystals and further to the appearance of $S\{11\bar{2}2\}$ faces on synthetic quartz crystals grown on seed [5.27]. Vicinal sectoriality is also reported on rhombohedral faces of calcite crystal [5.28]. The appearance of vicinal sectoriality due to impurity adsorption indicates that element partitioning is controlled by the growth kinetics.

Partitioning or the distribution of impurity elements is controlled by both thermodynamic factors and growth kinetics. Assuming growth under a constant thermodynamic condition, element partitioning is principally controlled by growth kinetics. The ratio of element partitioning between the ambient phase and crystal is defined by the effective distribution coefficient, K_{eff} . Elements with $K_{\text{eff}} < 1$ are incorporated less in the growing crystal and accumulate more in front of the growing crystal in the ambient phase, while those with $K_{\text{eff}} > 1$ are incorporated more into the crystal as growth proceeds. Burton et al. [5.1] indicated theoretically that K_{eff} depends on the normal growth rate R , the diffusion constant D , and the thickness of the diffusion boundary layer δ as

$$k_{\text{eff}} = \frac{k_0}{k_0 + (1 - k_0) \exp(-R\delta/D)}. \quad (5.3)$$

Since the normal growth rates differ depending on the crystallographic orientation and interface structures, element partitioning will be different between smooth and rough interfaces and among different crystallographic faces.

Fig. 5.12 Cathodoluminescence tomograph of cubo-octahedral crystal of HPHT synthetic diamond. CL intensity in $\{111\}$ growth sectors is high, whereas no or weaker CL intensity is seen in $\{100\}$ growth sectors, indicating selective and higher partitioning of nitrogen in morphologically more important $\{111\}$ growth sectors than in less important $\{100\}$ faces (courtesy of GAAJ)

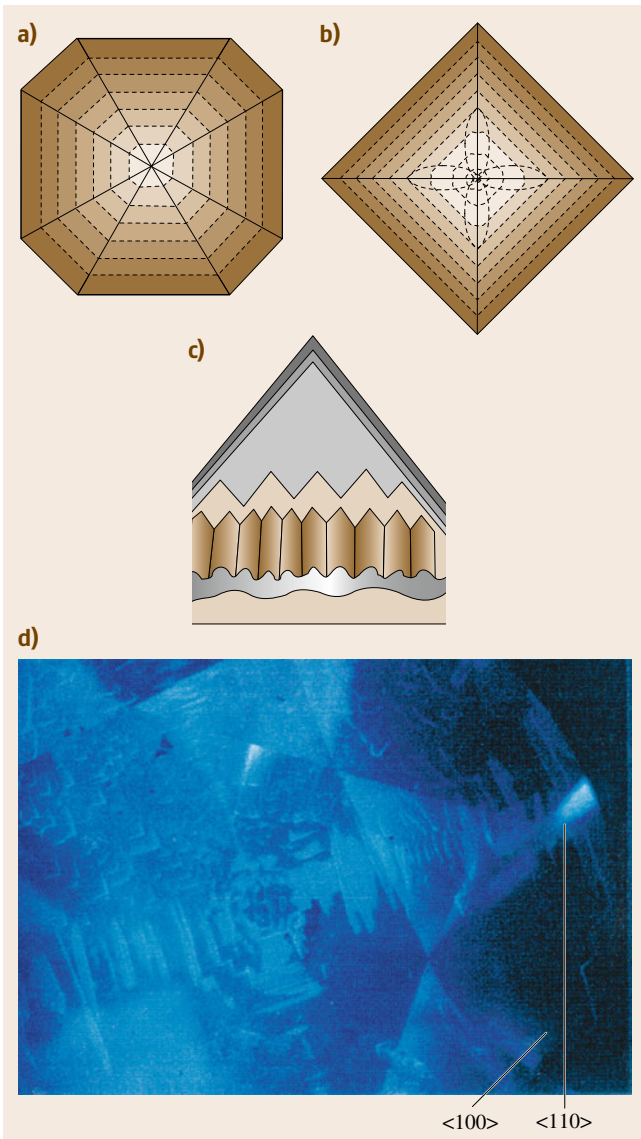

Fig. 5.13a–d Straight growth banding observable in the growth sectors corresponding to (a) two smooth interfaces and (b) one smooth interface and another rough interface, in which growth banding is not straight but hummocky. Transition of smooth to rough interface, followed by morphological instability of the interface to form cellular growth and the development of microfacets in the recovery process from rough to smooth interface, is indicated in (c). (d) CL tomography of a round, brilliant cut diamond, indicating the development of micro {111} facets during the recovery process from seed cuboid bounded by rough interfaces

The normal growth rate R of a rough interface is higher than that of a smooth interface. However, the lateral advancing rate v of growth layers on a smooth interface is much higher than the normal growth rate on a rough interface. The higher the growth rate or the step advancing rate, the higher the probability of incorporating impurity elements at the growth front. Therefore, it is anticipated that impurity elements with $K_{\text{eff}} < 1$ will be more concentrated in growth sectors of smooth interface than those of rough interface. This was initially observed in Si single crystals grown from the melt phase by Czochralski method. In melt growth of Si by CZ method, the solid–liquid interface follows an isothermal profile, the interface is mainly rough, and an adhesive-type growth mechanism operates principally. However, at the central portion of a growing single-crystalline boule, a facet of smooth {111} interface appears, forming a central, narrow growth sector formed by smooth interface surrounded by those formed by rough interface growth. It was found that Bi distributes more in the central growth sector of faceted growth on {111} smooth interface than in the major growth sectors of the rough interfaces. This anisotropic distribution of Bi was understood as due to the much higher advancing rate v of growth layers on a smooth interface than the normal growth rate R of a rough interface.

From the observation on Si crystal grown from the melt phase, it is anticipated that impurity elements with $K_{\text{eff}} < 1$ will be more concentrated in the growth sector of smooth face with the slowest normal growth rate than in growth sectors of both rough interface and smooth interface with lower morphological importance. Figure 5.12 shows an example demonstrating this: a CL tomograph of high-pressure high-temperature synthetic diamond crystal bounded by {111} and {100} faces showing brighter zones corresponding to higher concentration of nitrogen in {111} growth sectors than in {100} growth sectors, which show no CL intensity. In the growth of high-pressure high-temperature (HPHT synthetic) diamond, both {111} and {100} behave as smooth interfaces, but {111} is morphologically more important than {100} [5.29]. Natural diamonds also indicate higher concentration of nitrogen in smooth {111} growth sector than in rough {100} growth sector. In natural diamond growth, {111} behaves as a smooth interface, whereas {100} exclusively behaves as a rough interface. In synthetic quartz, Al impurity was found to be selectively adsorbed on growth

steps of certain vicinal faces of growth spirals developing on the morphologically most important $\{10\bar{1}0\}$ faces [5.27].

Impurity elements with $K_{\text{eff}} < 1$ accumulate more as growth proceeds, in the ambient phase, to form a concentration gradient in the diffusion boundary layer surrounding the growing crystal. This modifies the chemistry of the ambient phase in the diffusion boundary layer, affecting the normal growth rate, the critical driving force for 2DNG, diffusion rates, etc., and leads to the formation of a band with a gradient of impurity concentration parallel to the growing surface. Due to coupling of the accumulation of impurity on the growing interface, their diffusion, and the resulting change in the normal growth rate, an alternating succession of bands with varying concentration of impurity (and also point defects) appears parallel to the growing surface, even if the crystal grew under nearly constant growth conditions. Such bands may be less distinct and have nearly uniform and narrow spacing. When growth parameters change abruptly, a more distinct growth band is formed. So, within one growth sector, distinct but not uniformly spaced bands and less distinct but uniformly and narrowly spaced bands appear. Since these bands appear through growth and represent the morphology of the crystal at successive stages, this banding is called growth banding. Analysis of growth banding provides important information about how the crystal grew and the morphology changes throughout its growth process. Growth bands in the growth sectors of smooth interfaces exhibit straight banding, whereas in those of rough interface growth, hummocky growth banding appears (Fig. 5.13a,b). If a smooth interface transforms to a rough interface during growth due to a conditional change, and the rough interface changes to a smooth interface in further growth, the appearance of a wavy and hummocky band and its transformation to a cellular pattern, followed by transformation from a rough to smooth interface with the appearance of microfacets in the recovery process, may be traced by observation of growth banding (Fig. 5.13c,d). The evolution of the crystal morphology in the formation of single crystal may also be traced. Dissolution of earlier formed crystal followed by regrowth may be identified through the observation of the banding pattern in single crystal. All sorts of event may be discernible by the analysis of heterogeneities in single crystals. Figure 5.13a–c shows schematically a few cases to be expected, and Fig. 5.13d shows an actual example of the appearance of microfacets during the recovery process. Figure 5.14 shows schematically the internal morphology

Fig. 5.14 Trapeiche emerald (left) and ruby (right), formed by dendritic growth forming the skeleton of the crystal, followed by growth on smooth interface filling the interstices of dendritic arms (after [5.30,31])

ogy of emerald and ruby crystals, indicating earlier formation of core portion by 2DNG or spiral growth, on which dendritic growth took place to form the arms and branches, followed by 2DNG or spiral growth filling the interstices of the dendritic arms. These are called trapeiche emerald or ruby. Various terms are used to express the corresponding portions, as indicated in the figure [5.30, 31], but the growth mechanism and history are the same in both minerals. The skeleton and the size of the present crystal are determined by this growth history.

If a polyhedral crystal receives weak dissolution (etching), corners, edges, and outcrops of point and line defects are preferential sites to be attacked. The polyhedral crystal will be rounded off with etch pits on the surfaces. Straight growth banding observable in growth sectors is cut by the rounded external surface. All natural diamond crystals show rounded morphology and etch pits, indicating that their characteristic rounded forms are due to dissolution experienced during the ascent period from depth to the Earth's surface, during which they experienced pressure–temperature conditions labile for diamond. When dissolution occurs to form rounded crystal, on which regrowth later took place, earlier straight growth banding is intersected by rounded discontinuity, followed later by the appearance of microfacets and straight growth banding. A wide variety of internal morphology is encoun-

tered in polyhedral single crystals of natural minerals, and their growth and postgrowth histories can be

analyzed if their internal morphology is properly analyzed.

5.6 Perfection of Single Crystals

Dislocations are generated where lattice planes advancing from different sources meet with mismatches or displacements during growth. There can be various origins of lattice mismatches during the growth process of a crystal. In the nucleation stage the nucleus may be bounded by rough interfaces, but soon smooth interface starts to appear. Lattice mismatch may occur through this transformation from rough to smooth interface at the earliest stage of growth. When dendritic arms conjugate, or when solid or liquid inclusions are enclosed into the growing crystal, lattice mismatch occurs at places where they are enclosed. When bunched macrosteps advancing on smooth interface meet, lattice mismatch may also occur. In these cases, dislocations with large

Burgers vector are often generated on the growing surface. Since such dislocations are energetically unfavorable, they dissociate into many dislocations with elemental Burgers vector. When seed crystal is used, its surface provides preferential sites to generate new dislocations, since inclusions are likely trapped on etched seed surface, from where dislocations are newly generated, together with dislocations inherited from the seed. A variety of spatial distributions of dislocations can therefore be encountered in single crystals grown freely under unconstrained conditions and with seed crystal. When crystals grow in the interstices of solid crystals of other minerals, such as in the formation of metamorphic rocks, numerous dislocation centers will be

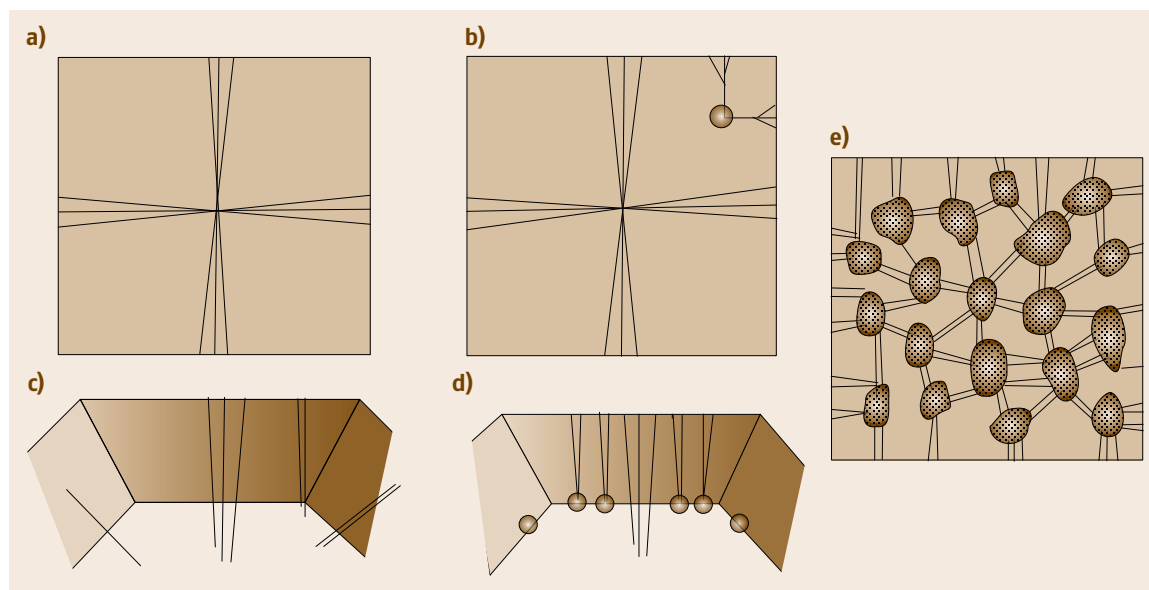

Fig. 5.15a–e Schematic illustrations of the spatial distribution of dislocations in single crystals. **(a)** Dislocations originating at the center of a crystal and radiating in a bundle nearly perpendicularly to the growing faces for energetic reasons. This is a representative distribution of dislocations observed in freely grown crystal in diluted vapor or solution phase under unconstrained conditions. **(b)** Dislocations are also generated from a point where an inclusion is enclosed. Dislocations with a large Burgers vector dissociate into many dislocations with elemental Burgers vector. **(c,d)** Comparison of the inheritance of dislocations in the seed to the newly grown portion **(c)** and the generation of new dislocations from inclusions formed on the seed surface **(d)**. **(c)** As-grown crystal is used as seed, whereas **(d)** etched crystal is used. **(e)** When growth occurs in the interstices of solid grains, such as expected in metamorphism, a single crystal may show a large number of points from where dislocations are generated

Fig. 5.16a–d How SiC crystals grow by the Acheson method (impure CVT) (a–c), and (d) by the Lely method (pure CVT or close to PVT). (a) Macro photograph of SiC crystals grown by the Acheson method, showing earlier dendritic growth followed by the appearance of {0001} face. (b) Ordinary reflection photomicrograph showing appearance of flat {0001} face through conjugation of microfacets of {0001} at the tips of dendrite arms, and (c) positive phase-contrast photomicrograph of growth spirals with larger and elemental (arrows) step heights, observable on flat {0001} surface such as shown in (b). Spiral steps originating from dislocations with larger Burgers vector show much brighter contrast than those originating from elemental (arrows) Burgers vector. Coexistence of growth spirals with larger and elemental Burgers vectors is due to the dissociation of dislocations with larger Burgers vector. (d) A positive phase-contrast photomicrograph showing an example of growth spirals commonly observed on SiC crystals synthesized by the Lely method. Arrows *a* and *b* indicate the direction to the center and the wall of the crucible, respectively, and *c* the spiral center. Step separation is eccentric from *c* to *a* and from *c* to *b*, due to the flow of source vapor (gradient) over the surface [5.32]. Bunching of spiral steps and perturbation of step morphology is seen in direction *b* ◀

observed in the crystals. These are illustrated schematically in Fig. 5.15, and a few representative examples will be described in the following.

A wide variety of spatial distributions of dislocations are observed in freely grown single crystals, such as natural minerals or crystals grown from solution phase. Since the spatial distribution of dislocations in single crystals provides important information relating how the crystal grew and what sort of conditional changes took place during its growth history, we may analyze these based on their investigations, coupled with observations of its surface microtopography and internal morphology. Three examples are now described.

SiC crystals synthesized by the Acheson method grow as dendrite at the initial stage on the wall of the reaction crucible. The dendritic arms conjugate together and the basal {0001} face starts to appear, inclined with respect to the length of the dendrites [5.33]. This can be seen clearly in Fig. 5.16a,b. Dislocations generated at the points where dendritic arms are close usually have large Burgers vector and dissociate into many dislocations with elemental Burgers vector. As a result, on the {0001} surface, coexistence of growth spirals with step heights corresponding to large and elemental Burgers vector is often observed. Figure 5.16c shows an example of growth spirals often observed on SiC crystals grown by the Acheson method. In the case of SiC crystals synthesized by the Lely method, more ideal growth spiral originating from independent dislocation are generally observed. However, these spirals often show eccentric step separation (Fig. 5.16d) due to the surface supersaturation gradient [5.32].

Figure 5.17 shows an x-ray topograph of a slice cut perpendicular to the *c*-axis of a prismatic quartz crystal occurring in a granitic pegmatite. Growth sectors corresponding to {10 $\bar{1}$ 1}, {0111}, and {10 $\bar{1}$ 0} faces and sector boundaries, growth banding, and dislocation bundles generated from inclusions are observed in contrast images. Distinct anisotropy in the development of growth sectors, in the spacing of growth banding, and in the distribution and density of inclusions and dislocation bundles can be noticed among crystallographically equivalent growth sectors. The observed anisotropies imply that the quartz crystal grew under the effect of solution flow. On the growing {10 $\bar{1}$ 1} and {10 $\bar{1}$ 0} faces, facing the solution flow, more inclusions are precipitated, from where more dislocations are newly generated than on the surface growing on the opposite side.

Figure 5.18a,b shows x-ray and CL tomographs of a pear-shaped brilliant cut diamond, respectively. The squarelike pattern at the center in Fig. 5.18a is an outline of a tiny cuboid crystal whose overall

Fig. 5.17 X-ray topograph of a slice cut perpendicular to the *c*-axis of a prismatic quartz crystal from pegmatite (x-ray topography, courtesy of T. Yasuda)

form is close to cubic, although not bounded by flat {100} faces but by rough, near-{100} faces. The cuboid was formed elsewhere and transported into a different growth environment, where it acted as a seed for further growth under the new conditions. In Fig. 5.18a, it is noted that dislocations are newly generated on the surfaces of the seed cuboid and radiate in the form of bundles running parallel to $\langle 100 \rangle$, although there are also a few dislocations inherited from the seed. The Burgers vector of these dislocations is 100, which is different from those generally observed in most gem-quality diamonds, i.e., 110. In Fig. 5.18b, it is seen that growth of diamond on the seed transforms from rough {100} to smooth {111} morphology through the appearance of many {111} microfacets, indicating morphological evolution in the recovery process from rough to smooth interfaces [5.34]. The most likely place where the seed cuboid was formed is considered to be in ultrahigh-pressure high-temperature (UHPHT) metamorphic rocks formed by plate subduction. In these metamorphic rocks, minute diamond crystals are formed in porphyroblastic (crystals developed much larger than the coexisting ones) silicate minerals, such as garnet and zircon [5.35]. It is argued that these diamond crystals were formed in silicate-carbon liquid droplets formed by partial melting of porphyroblastic silicate mineral containing unmelted carbon [5.34]. The carbon source is assumed to be of organic origin, subducted from oceanic sediments. This explains the much higher concentration of diamond, attaining up to 2% in UHPHT metamorphic rock, as compared with the very low content of diamond (on the order of ppm) in mantle-originated ultramafic rocks. When these UHPHT metamorphic rocks are subducted deeper and digested in magma in the mantle, this diamond acts as a seed on which further diamond grows under much lower driving force conditions [5.34]. This example demonstrates that a large-scale geological movement or cycle is recorded in the form of the internal morphology, perfection, and homogeneity within a small crystal, provided that this information can be properly deciphered.

Natural diamond crystals experience a severe post-growth history. They grew in the depth of the Earth, under diamond-stable high-pressure high-temperature conditions, in silicate or carbonate solution phase, and were uplifted at great speed by volcanic action, to be quenched as a metastable phase through volcanic eruption. In the rapid ascent process, diamond crystals suffer partial dissolution, resulting in rounded forms and the formation of etch pits. They also experience plastic de-

Fig. 5.18a,b X-ray topograph (a) and cathodoluminescence tomography (b) of a pear-shaped brilliant cut diamond. (a) demonstrates that most of this crystal was formed by growth under new conditions on a seed cuboid, seen at the center, which was formed elsewhere under different conditions and transported to the new conditions. Most dislocations with Burgers vector 100 are generated on the seed surface. (b) demonstrates that the morphology transformed from rough cuboid to octahedral bounded by smooth {111} faces via the appearance of a series of {111} microfacets, which is discernible from the distribution of brighter CL contrast corresponding to selective partitioning of impurity nitrogen to smooth {111} faces

formation, forming dislocation tangles and exsolution (precipitation) of impurity nitrogen. Natural diamonds are classified into type I and II, which differ in various physical properties related to their different nitrogen content. Type I contains higher nitrogen content and thus corresponds to C-N alloy, whereas type II contains

far less nitrogen and corresponds to pure C. Due to this difference, their plastic deformation behavior is different, type I being plastically stronger than type II. As a result, when both types experience the same stress history, type II suffers greater plastic deformation. Among natural diamond crystals, type II crystals exclusively show irregular forms without crystallographic faces, whereas type I crystals exhibit polyhedral form with rounded corners and edges. Type I crystals exhibit dislocation bundles radiating from the center of a crystal on x-ray topographs, whereas type II crystals show bending with portions of slightly different orientations, indicating that type II crystals are heavily deformed compared with type I crystals, and sometimes even broken into pieces [5.36].

Observations on the perfection, homogeneity, and internal morphology of natural diamond crystals

demonstrate that the whole growth and postgrowth histories are recorded in small crystals of diamond. We can see in a tiny diamond crystal the whole large-scale geological movements experienced by the crystal, provided that this record can be properly deciphered. Understanding the crystal growth mechanism, morphology, perfection, and homogeneity form the basis for properly reading this message sent from the depth of the Earth. It also indicates that natural and synthetic gemstones, including diamond, can be discriminated by these investigations, since both grow in solution phases but with different solvents (natural diamonds from silicate or carbonate, synthetic diamonds from metallic) and have different growth histories, although both are the same crystal species [5.29]. It is also possible to fingerprint two brilliant cut diamonds obtained and fashioned from one rough stone [5.34].

6. Defect Formation During Crystal Growth from the Melt

Peter Rudolph

This chapter gives an overview of the important defect types and their origins during bulk crystal growth from the melt. The main thermodynamic and kinetic principles are considered as driving forces of defect generation and incorporation, respectively. Results of modeling and practical in situ control are presented. Strong emphasis is given to semiconductor crystal growth since it is from this class of materials that most has been first learned, the resulting knowledge then having been applied to other classes of material.

The treatment starts with zero-dimensional defect types, i.e., native and extrinsic point defects. Their generation and incorporation mechanisms are discussed. Micro- and macrosegregation phenomena – striations and the effect of constitutional supercooling – are added. The control of dopants by using the nonconservative growth principle is considered. One-dimensional structural disturbances – dislocations and their patterning – are discussed next. The role of high-temperature dislocation dynamics for collective interactions, such as cell structuring and bunching, is shown. In a further section second-phase precipitation and inclusion trapping are discussed. The importance of in situ stoichiometry control is underlined. Finally two special defect types are

treated – faceting and twinning. First the interplay between facets and inhomogeneous dopant incorporation, then main factors of twinning including melt structure are outlined.

6.1 Overview

The quality of single crystals and devices made therefrom are very sensitively influenced by structural and atomistic deficiencies generated during the crystal growth process. It is the chief task of the crystal grower to determine the conditions for their control, minimization or even prevention. Crystalline imperfections include point defects, impurity and dopant inhomogeneities, dislocations, grain boundaries, second-phase and foreign particles, twins, and so on. Some defect types, such as point defects, are in thermodynamic equilibrium and are therefore always present. This is due to the thermal excitations and entropic disordering forces at temperatures $T > 0$. Further, each crystal is bounded by surfaces with interface characteristics deviating from

geneities, dislocations, grain boundaries, second-phase and foreign particles, twins, and so on. Some defect types, such as point defects, are in thermodynamic equilibrium and are therefore always present. This is due to the thermal excitations and entropic disordering forces at temperatures $T > 0$. Further, each crystal is bounded by surfaces with interface characteristics deviating from

volume perfection. These facts prevent the growth of ideal, perfect crystals. Hence, in practice only optimal crystals are achievable.

Over more than a half-century of development of melt growth, most of the important defect-forming mechanisms have become well understood. Historical aspects of this progress were recently summarized by Hurle and Rudolph [6.2, 3]. Today, there exists an enormous knowledge about defect genesis in as-grown crystals supported by demanding theoretical fundamentals and computational modeling. As a result, the present state of technology makes it possible to produce crystals of remarkably high quality with tailored parameters fitting the demands of the device industry quite well. However, that is not to say that all problems are already solved. Thus, the present chapter will also cover still open questions and help to find optimal measures of defect engineering.

In this section first the defect types will be categorized in the classical manner of zero-, one-, two- and three-dimensional defects. Then some effects of defects on device properties will be covered.

6.1.1 Defect Classification

The international standard crystal lattice defects (defects in short), sketched in Fig. 6.1, are usually classified according to their dimension as follows [6.1].

Zero-dimensional defects are *point defects*, often referred to by the unpopular name *atomic-size defects*, which include the intrinsic defect types va-

cancies, *interstitials*, and in compounds, *antisites*. If extrinsic atoms are invoked unintentionally (as residual *impurities*) or intentionally (as *dopants*) they occupy interstitial or substitutional (lattice) positions. At growth temperatures, point defects are isolated and usually electrically charged. The charge state of point defects can lead to their interaction with electrically active dopants, creating *point defect complexes*.

One-dimensional defects include all kinds of *dislocations*, i. e., perfect screw and edge dislocations, mixed dislocations, partial dislocations (always in connection with a stacking fault), and dislocation loops. The propagation and interaction of dislocations over mesoscopic distances is the subject of *dislocation dynamics*. The collective screening behavior of dislocations contributes to their rearrangement in dipoles, walls, and networks, as well as under simultaneous stress in cell patterns and bundles. Whether the cell patterning is driven energetically or by a self-organizing process in the framework of equilibrium or nonequilibrium thermodynamics, respectively, is still the subject of research.

Two-dimensional defects are grain boundaries, stacking faults, phase boundaries, facets, and twins. A *low-angle grain boundary* structure is formed by the mechanism of dynamic polygonization and still belongs conventionally to a single-crystalline state. In contrast, *large-angle grain boundary* structures are formed by polycrystalline growth due to spontaneous or foreign nucleation processes. *Facets* are formed along atomically smooth planes, indicating the tendency of high-quality crystals to form polyhedra. They cause extrinsic point-defect and temperature-field inhomogeneities due to their fast lateral growth kinetics and enhanced radiation reflectivity, respectively. Grown-in *twins* are originated by a false stacking sequence, especially when the two-dimensional nucleus on a growing facet is disoriented.

Three-dimensional defects include second-phase particles (*precipitates*), intrinsic vacancy conglomerates (*microvoids*), and foreign particles (*inclusions*). It is important to differentiate between precipitates and inclusions, which are mostly confused in the literature. Whereas precipitates and microvoids are formed by supersaturation-driven condensation of intrinsic point defects, i. e., interstitials and vacancies, respectively, inclusions are melt–solution droplets, gas bubbles, and foreign microparticles incorporated at the growing melt–solid interface, especially when the melt composition deviates from the congruent melting point or contaminations are present. The two types of defects

Fig. 6.1 Scheme of real crystal lattice with defects (after Föll [6.1]). a – interstitial impurity atom, b – incongruous inclusion, c – edge dislocation, d – self-interstitial atom, e – vacancy, f – vacancy-type dislocation loop, g – precipitate of impurity atoms, h – interstitial-type dislocation loop, i – substitutional impurity atom

usually differ in their size, being 10–100 nm for precipitates and 1–10 μm for inclusions.

6.1.2 Consequences of Crystal Defects for Devices

Defects have deleterious effects on the performance, reliability, and degradation behavior of devices. Following the early classification of *Pick* [6.4] defects influence the:

- Structural properties (vacancies and interstitials may change the lattice constant; grains affect the single crystallinity)
- Chemical properties (defects participate in chemical reactions; their redistribution causes composition inhomogeneities)
- Electronic properties (defects occupy a specific state in the band structure)
- Scattering properties, i.e., the defect interacts with particles (phonons, photons of any energy, electrons, positrons, etc.).

As can be seen, the interaction processes are many-sided and require wide interdisciplinary research with direct correlation to advanced technical progress. In fact, a large part of the worldwide technology progress depends on the control and manipulation of defects in crystals, above all in the semiconductor and optical industries, but also in biotechnology and many others. There are an enormous number of monographs and publications dealing with this topic. In the following, however, only selected examples of correlation between device characteristics and defects will be touched upon. An instructive review about defects in semiconductors and their electronic properties is given by *Mahajan* [6.5].

Point defects determine the basic properties of the materials used in devices. Parameters such as the specific resistance of semiconductors, conductance in ionic crystals, or diffusion properties in general, which may appear to be intrinsic properties of a material, are in fact defect dominated. In optical devices the transmittance, birefringence, and refractive index are influenced by the density and distribution of intrinsic and extrinsic point defects very sensitively. For instance, high-quality electrooptical and nonlinear optical devices of LiNbO_3 require an extremely accurate constant Li/Nb ratio (congruent composition) to ensure birefringence homogeneity of $(5\text{--}7) \times 10^{-5}$ [6.6]. Intrinsic point defects can influence the conduction type in semiconductors. For instance, vacancies and interstitials in silicon can

have distinct acceptor and donor energy levels within the bandgap, respectively [6.5]. As_{Ga} antisites in GaAs are deep-level donors (EL2). Their density, which depends on the deviation from stoichiometry, determines the compensation doping level by a shallow acceptor (carbon) in order to ensure semi-insulating property in high-frequency circuits [6.7]. Point defects and their diffusion have a strong impact on the noise characteristics through an interaction of charge carriers with the fluctuating local ionic surrounding. In (Hg,Cd)Te infrared photodiodes there is a linear dependence between the $1/f$ noise power and the fraction of ionized Hg vacancies providing p-type conductivity [6.8]. In some cases, however, a redistribution of extrinsic defects is even desirable. For instance, in micro laser waveguides for integrated optics (e.g., LiNbO_3 fibers) the accumulation of certain dopants (Mg) near the surface helps to concentrate the laser beam in the center by the effect of refractive-index cladding [6.9].

As is well known, *dislocations* are defects influencing the quality of nearly all types of devices insofar as they act as getters for point defects and dopants so that they can contribute to electrical and chemical inhomogeneity. They decrease transmission in lenses, affect light intensity in laser rods, and influence the mechanical stability in piezo- and acoustoelectric transducers. Dislocations in substrates are transformed as threading dislocations into the epitaxial layers grown on them. When an overcritical misfit between the lattice parameters of a substrate and epilayer exists, misfit dislocations are generated at their interface. Both threading and misfit dislocations play an important role in the rapid degradation of (Ga,Al)As/GaAs lasers. The degradation of light-emitting semiconductor diodes and lasers follows from the fact that dislocations cause nonradiative recombination and decrease luminescence efficiency. They reduce the minority-carrier lifetime and, when the spacing between them is comparable to the diffusion length, luminescence efficiency breaks down [6.10]. Dislocations can contribute to electronic behavior, especially, in diamond and zincblende structures where the cores of glide and shuffle set dislocations are associated with dangling bonds [6.5]. Recently it was shown that small screw dislocations and threading edge dislocations are the most common defects in 4H-SiC homoepitaxial devices produced by chemical vapor deposition on SiC substrates. As their densities increase, the breakdown voltage of Schottky devices is decreased [6.11]. The central parameter of field-effect transistors (FETs) is the turn-on threshold voltage (V_{th}), the fluctuations of which across a wafer

Table 6.1 Selected examples of defects in melt-grown crystals demonstrating their adverse effect on device quality (BPT – bipolar transistor, PD – photodiode, IR – infrared, KTN – $K(\text{Ta}_x\text{Nb}_{1-x})\text{O}_3$, ME – microelectronics, MC – multicrystalline, LED – light-emitting diode, LD – laser diode, PVE – photovoltaic efficiency, UV – ultraviolet, YAG – $\text{Y}_3\text{Al}_5\text{O}_{12}$, MOS – metal–oxide–semiconductor, HBT – heterostructure bipolar transistor, MMIC – monolithic microwave integrated circuit, NLO – nonlinear optic, AO – acoustooptic)

Material	Defect type	Device version	Adverse effect
<i>Zero-dimensional</i>			
Si	Interstitial Si_i	BPT, PD	Ionized donor level, carrier traps
CdTe	Vacancy V_{Cd}	Radiation detector	Shallow donor reducing electrical resistivity
(Hg,Cd)Te	Vacancy V_{Hg}	IR photodiodes	Increased $1/f$ noise power
GaAs	Antisite As_{Ga}	Radiation detector	Deep level trap reducing carrier lifetime
KTN	Ta-rich striations	Optical modulator	Optical inhomogeneity, refractive index change
<i>One-dimensional</i>			
Si	Dislocation loops	ME circuits	Swirl formation, shorts
Si	Dislocations	MC-Si solar cell	Affecting minority carrier lifetime
GaAs	Dislocations	LED, LD	Nonradiative recombination
(Cd,Zn)Te	Cell structure	Radiation detector	Impediment of electron transport
<i>Two-dimensional</i>			
Si	Grain boundaries	MC-Si solar cell	Decreasing PVE by impurity (Fe) gettering
InP	Twins	ME circuits	Decreasing usable crystal gain
CaF_2	Grain boundaries	UV lenses	Light scattering and radiation damage
YAG	Facets	Solid state laser	Refractive index variation, optical loss
<i>Three-dimensional</i>			
Si	V_{Si} clusters (voids)	MOS circuits	Gate oxide degradation by local thinning
GaAs	As precipitates	HBT, MMIC	Impairment of wafer polishing and epitaxy
LiNbO_3	Eutectic inclusions	NLO modulators	Light scattering, birefringence impairment
PbMoO_3	Pb-rich inclusions	AO transmitter	Light scattering, reduced transmission

must be minimal to ensure high device yield. In ion-implanted GaAs FETs a shift of V_{th} around dislocations was observed which has been explained not only by the dislocation presence but also by the enhanced GaAs antisites and As interstitials on dislocations [6.12]. Thus, in order to remove the decorating defects from dislocations today each as-grown GaAs crystal is postannealed before it is applied for device technology. Note that dislocations themselves are practically immune to post-growth thermal treatment.

Cellular structures of dislocations and *grain boundaries* are two-dimensional defects responsible for harmful optical and electrical inhomogeneities. For instance, across semi-insulating {100} GaAs wafers a mesoscopic resistivity variation is observed due to the accumulation of As_{Ga} antisite defects (EL2) within the cell

walls [6.13]. Subgrain boundaries also impede the electron transport, as in $\text{Cd}_{1-x}\text{Zn}_x\text{Te}$ radiation detectors [6.14]. In general, since grain boundaries are defects in the crystal structure, they tend to decrease the electrical and thermal conductivity of the material. Additionally, the high interfacial energy and relatively weak bonding in grain boundaries makes them preferred sites for the onset of corrosion and the precipitation of new phases from the solid. The presence of a small-angle grain boundary structure in melt-grown LiF crystals prevents their use in monochromators and x-ray analyzers due to the high light and x-ray diffraction scatterings, respectively [6.15]. Increasing quality is demanded for CaF_2 lenses, which are used in deep-ultraviolet (UV) semiconductor microlithography. The stepwise reduction of the exposing wavelength down to

157 nm, correlating with the smallest circuit structure size, requires a dramatic improvement of the growth and annealing conditions of CaF_2 crystals. The highest transmission and lowest radiation damage can be only achieved when the crystals are free of grain boundaries [6.16].

It is noteworthy that there is also a certain interest in crystals with mosaic structure. For instance, diffraction lenses for nuclear astrophysics show an improved reflection power when crystals with mosaicity of 20–50 arcs (e.g., $\text{Ge}_{1-x}\text{Si}_x$) are used [6.17]. Further, in nanocrystalline materials, controlled reduction of grain size to nanometer scale leads to many interesting new properties including a great increase in strength [6.18]. Therefore, the further development of knowledge about collective dislocation interactions in growing crystals is of general practical relevance for both targets, i.e., both suppressing and promoting cellularity.

6.2 Point Defects

At all temperatures above absolute zero, equilibrium concentrations of vacancies, self-interstitials, and in the case of compound semiconductors, antisite defects will exist. This is because point defects increase the configurational entropy, leading to a decrease in free energy. Thus, such native point defects are always presented in as-grown crystals. However, their concentration can be influenced by the growth conditions very sensitively. In silicon a nearly defect-free situation due to vacancy–interstitial annihilation can be achieved by selection of a certain relation between the temperature gradient and crystallization rate. In compound crystals *in situ* control of stoichiometric growth conditions can minimize the intrinsic defect density.

Extrinsic point defects are incorporated arbitrarily or deliberately as impurities or dopants, respectively. Today, the purification techniques of the starting charge materials are of such a high standard that total residual impurity concentrations fall below the frozen-in contents of native point defects. In elemental crystals (e.g., silicon) purity levels less than 10^{14} cm^{-3} and in compound crystals (e.g., GaAs) values below 10^{15} cm^{-3} can be achieved. Therefore, their influence on the crystal lattice parameter and electrical parameters is of secondary significance. Of course, due to a contaminated growth atmosphere or because of strong chemical affinities it can happen that certain arbitrary elements are introduced in enhanced concentrations, such as oxygen in

Precipitates and *inclusions* are second-phase particles of autonomous crystallographic structure and chemical composition forming an interfacial boundary with the matrix material. They induce local parameter and stress fluctuations and, therefore, mostly misfit dislocations [6.19,20]. In liquid encapsulation Czochralski (LEC) GaAs substrates arsenic precipitates affect the device properties of epitaxial-type metal-semiconductor field effect transistors (MESFETs). They also cause the formation of small surface oval defects on molecular beam epitaxy (MBE) layers [6.5]. Principally, inclusions impair the surface quality of wafers during the polishing process. In lenses and backside radiation detectors they reduce the transmission quality by light scattering.

Table 6.1 summarizes selected correlations between device quality impairments and the responsible defect types.

CaF_2 or carbon in silicon, for example. In contrast, for light-emitting devices the required dopant concentrations markedly exceed those of impurities and usually exceed 10^{18} cm^{-3} or amount even to 10^{21} cm^{-3} , as for Cr^{3+} in ruby laser crystals. In these cases homogeneous incorporation is of essential technological importance but is complicated by the natural segregation effect that may lead to macro- and microdistributions. A characteristic structural impairment during growth from doped or incongruent melts can arise from constitutional supercooling – the interplay between rejected dopants or excess atoms, diffusion, and heat transfer at the growing melt–solid interface. Growing-in dopants interact with native point defects, which are isolated and mostly ionized at growth temperatures. As a result, the physical efficiency of dopants can be reduced by compensation and complex formation.

It is the aim of the crystal grower to understand these interactions on the atomic scale and determine their correlations to the growth conditions in order to master chemical and electronic homogeneities as much as possible.

6.2.1 Native Point Defect Generation

Thermodynamics

All thermodynamic processes strive to minimize the free energy. Applied to the crystallization process this

means that the single-crystalline state is a normal one because the free thermodynamic potential G (free potential of Gibbs) is minimal if the *crystal growth units* (atoms, molecules) are perfectly packed in a three-dimensional ordered crystal structure, i. e., the atomic bonds are saturated regularly. Because the sum of the atomic bonds yields de facto the potential part H , i. e., the enthalpy part of the internal crystal energy $U = H - PV$ (where P is pressure, and V is volume), the process of ordering responsible for adjustment of the *crystal periodicity* is characterized by the minimization of enthalpy ($H \rightarrow \min$).

On the other hand, however, an ideally ordered crystalline state would imply an impossible minimal entropy S . Thus, the opposite process of increasing entropy, i. e., disordering ($S \rightarrow \max$) gains relevance with increasing temperature T . This is expressed by the basic equation of the thermodynamic potential of Gibbs

$$G = U + PV - TS = H(\downarrow) - TS(\uparrow) \rightarrow \min. \quad (6.1)$$

Hence, crystallization is composed of two opposite processes:

- i) Regular
- ii) Defective arrangement of the *growth units*.

Considering this dialectics of ordering and disordering forces at all temperatures above absolute zero it is not

possible to grow an absolutely perfect crystal. In reality *no ideal* but only an *optimal* crystalline state can be obtained. In other words, in thermodynamic equilibrium the crystal perfection is limited by incorporation of a given concentration of native point defects n .

Neglecting any effects of volume change, defect type, and defect interplay, at constant pressure the equilibrium defect concentration n can be determined from the change of thermodynamic potential by introducing the defect as

$$\Delta G = \Delta H_d - \Delta S_d T \rightarrow \min, \quad (6.2)$$

with $H_d = nE_d$, the change of internal energy due to the incorporation of n defects, depending on the total defect formation energy E_d , and $S_d = k_B \ln\{(N!)/[n!(N-n)!]\}$ the accompanying change of entropy (configurational entropy), where k_B is the Boltzmann constant and N the total number of possible sites. After substitution and application of Stirling's approximation for multiparticle systems such as a crystal ($\ln N! \approx N \ln N$, $\ln n! \approx n \ln n$, $\ln(N-n)! \approx (N-n) \ln(N-n)$) (6.2) becomes

$$\Delta G = nE_d - k_B T \times [N \ln N - n \ln n - (N-n) \ln(N-n)]. \quad (6.3)$$

Setting the first derivative of (6.3) as $\partial \Delta G / \partial n = 0$ to yield the energetically minimum defect concentration n_{\min} , and considering $N \gg n$, the *perfection limit* of a crystal is

$$n_{\min} = N \exp\left(\frac{-E_d}{k_B T}\right), \quad (6.4)$$

which is exponentially increasing with temperature. Setting $N = 5 \times 10^{22} \text{ atoms cm}^{-3}$ and $E_d = 1 \text{ eV}$ (the vacancy formation energy in metals) the minimum defect concentrations n_{\min} at 1000 and 300 K are about 5×10^{17} and 10^6 cm^{-3} , respectively. Note that, in the case of formation of vacancy–interstitial complexes (Frenkel defects), the value of $n_{\min}^{(F)}$ is somewhat modified and yields $\sqrt{N_{is} N} \exp(-E_d^{(F)}/k_B T)$, where N_{is} is the total number of interstitial positions depending on the given crystal structure, and $E_d^{(F)}$ is the energy of formation of a Frenkel defect. More fundamental details are given in Kröger's compendium [6.21], which remains even today one of the basic guides for the crystal grower.

Figure 6.2a,b shows the functions $\Delta G(n)$ and $n_{\min}(T)$ schematically. Due to the limitation of diffusion rate, a certain fraction of high-temperature defects

Fig. 6.2 (a) Schematic illustration of the equilibrium defect concentration (*perfection limit* n_{\min}) obtained by superposition of defect enthalpy H_d and entropy S_d using (6.2–6.4). (b) Minimum defect concentration versus temperature at various defect energies E_d according to (6.4). Dashed lines show the *freezing-in* courses of high-temperature defects for different migration coefficients D_s

freeze in during the cooling-down process of as-grown crystals (broken lines) and exceed the equilibrium concentration at room temperature markedly (Fig. 6.2b). In other words, in practical cases the intrinsic point-defect concentration is still far from thermodynamic equilibrium.

In principle, the total defect formation energy consists of various factors: $E_d = E_{\text{form}} + U_{\text{vib}} + S_{\text{vib}}T$ where E_{form} is the relevant defect formation energy, and U_{vib} and S_{vib} are the energy and entropy terms for the vibration contributions to the free energy. Of course, each contribution in its turn depends on temperature. Their exact experimental determination requires high-purity crystals and extremely precise analytical techniques, for instance, measurements of the thermal dependence of dilatation combined with precision x-ray analysis of the lattice constant. The native point defect concentration is proportional to the difference between the relative increase of length and the change of the lattice constant as $n \sim (\Delta L/L - \Delta a/a)$, whereas a positive or negative amount identifies the prevailing presence of vacancies or interstitials, respectively. No dilatation effect appears when the number of vacancies equals the number of interstitials. In principle, such measurements and most others begin to fail at defect concentrations below $\approx 10^{17} \text{ cm}^{-3}$. Therefore, theoretical treatments come to the fore, e.g., quasichemical, molecular dynamics (MD), ab initio, and first-principle calculations. Table 6.2 shows the formation energies and entropies of native point defects near the melting point in some important materials. The activation energies of defect migration are also given.

Note that these values for compound semiconductors differ in the literature markedly and Table 6.2 is only of approximate character. Additionally, one has to consider the multiple charge stages of native defects showing various energies depending on the position of the Fermi level [6.24].

It is clear that a given native point-defect content corresponds to each crystalline phase, like a *solute component* in a system with ideal mixing. Compound materials show a phase extent, termed the existence or homogeneity region, that deviates from the stoichiometric composition by a certain value. Assuming a conservative compound system AB with defect balance, the maximum deviation δ can be expressed in terms of the concentrations of the native point defects in each sublattice as [6.30]

$$\delta = \delta A - \delta B = \{[A_i] - [V_A] + 2[A_B] - 2[B_A]\} - \{[B_i] - [V_B] + 2[B_A] - 2[A_B]\}, \quad (6.5)$$

where $[A_i]$, $[B_i]$, $[V_A]$, $[V_B]$, $[A_B]$, and $[B_A]$ are the interstitial, vacancy, and antisite contents of A and B, respectively. In simple terms, by using (6.4) for each defect type in (6.5) the maximum equilibrium defect solubility in a given AB crystal at each temperature becomes identical to the solidus curve of the existence region in the phase diagram. Table 6.3 shows the maximum phase extents of some compound materials. As can be concluded from (6.4), in a cooling crystal the solidus curves take a retrograde course leading under realistic cooling rates to freeze in of high-temperature nonequilibrium defects (Fig. 6.2b). In standard-grown

Table 6.2 Selected formation energies, entropies, and activation energies of migration in selected materials (A, B_i – interstitial, $V_{A,B}$ – vacancy, A_B – antisite, k_B – Boltzmann constant, $^{\pm i}$ – charge stage and E_f in the mid-gap)

Material	Defect	Formation energy E_f (eV)	Formation entropy S_f (k)	Activation energy of migration E_m (eV)	Reference

compound crystals the real intrinsic point-defect concentration at room temperature is between 10^{15} and 10^{17} cm^{-3} . This is about 7–9 orders of magnitude higher than the calculated values in thermodynamic equilibrium (if E_d is assumed to be 1–2 eV).

For silicon crystals near to the melting point it is accepted that vacancies and interstitials are simultaneously present in concentrations of about 10^{14} – 10^{15} cm^{-3} and that they can recombine very rapidly [6.32]. In the end, the ratio between them within the cooled crystal is determined by the relation of the atomistic transport processes (e.g., diffusion and thermodiffusion), the recombination rate, and the applied growth parameters (e.g., the temperature gradient and pulling velocity). The situation in compound materials, e.g., semiconductors such as $A^{\text{III}}B^{\text{V}}$ and $A^{\text{II}}B^{\text{VI}}$, is more complicated and less well studied. The equilibrium point defect concentrations at the melting point tend to be much higher than in Si. Hurle's calculations [6.30, 33] in GaAs of the concentrations of the principal native point defects at the melting temperature yield values about 10^{17} – 10^{19} cm^{-3} for $[V_{\text{Ga}}]$, $[Ga_i]$, and $[As_i]$, $[V_{\text{As}}]$, respectively. This is comparable to or even greater than the intrinsic carrier concentrations. Due to their isolated, and usually electrically charged, states they can influence the position of the Fermi level. This results in a complex interaction between electrically active dopants and the native point defects, which can exist in more than one charge state (Sect. 6.2.2).

Generation and Incorporation Kinetics

Principally, increasing the temperature raises the probability of thermal (vibrational) and entropy-driven (configurational) generation of Frenkel defects. Depending on the temperature gradients acting along the crystal and the cooling rate the initially coincident concentrations of vacancies and interstitials can differ markedly due to differing migration rates (Table 6.2). As a result, one defect type can move to the crystal surface, leaving defects of Schottky type. Further, during the crystallization process, point defects can be incorporated from the melt at the propagating melt–solid interface. Hence, one has to distinguish between:

- Intrinsic defect generation
- Incorporation from outside.

In any case, the principles of both energy minimization and electrical neutrality act as *regulators* of concentration and charge balancing as far as equilibrium conditions occur. Lowering the energy enhances the recombination probability of interstitials and vacancies during the cooling-down process of the growing crystal. Heat and mass flows, however, can lead to deviations from thermodynamic equilibrium.

During crystal pulling from the melt or unidirectional solidification, native point defects undergo various types of transport kinetics, i.e., capture at the interface due to the crystal translation or phase boundary propagation (often designated *convection*), Fickian diffusion by jumping via interstitial sites, kick-out or vacancy occupation mechanisms, and temperature-gradient-driven thermal diffusion (the Soret effect). Until now silicon is the material best studied. The prevailing transport mode at each temperature and in each crystal region has been estimated by dimensionless numbers of point defect dynamics [6.34]. The numbers of Péclet $Pe_{I,V} = \nu L / D_{I,V}(T)$, Damköhler $Da_{I,V} = k_r C_{V,I}^{\text{eq}}(T) L^2 / D_{I,V}(T)$, and Soret $ST_{(I,V)} = D_T / D_{I,V}(T) \approx \nu k_B T^2 / H_{I,V}^F G_T D_{I,V}$ compare the convection, recombination, and thermodiffusion, respectively, with Fickian diffusion, where ν is the crystal growth velocity, L is the characteristic length, k_r is the recombination reaction constant, $C_{V,I}^{\text{eq}}$ is the equilibrium concentration, D_T is the coefficient of thermodiffusion, $D_{I,V}(T)$ is the coefficient of Fickian diffusion of interstitials and vacancies, k_B is the Boltzmann constant, T is absolute temperature, $H_{I,V}^F$ is the formation enthalpy, and G_T is the temperature gradient at the melt–solid interface. Setting the parameters for silicon [6.23, 34] one can see that convective and Fickian diffusion flows are comparably strong and compete with each other in the hot crystal section, that recombination proceeds very fast at high temperatures, but that thermodiffusion contributes only marginally. Thus, variations of the pulling rate can shift point-defect transport between convection- and diffusion-dominated regimes.

As was proved experimentally [6.35], at high pulling rates the flux of vacancies dominates over that of self-interstitials. On the other hand, at low pulling rates or with high temperature gradients, interstitials are in excess. This fact is of high significance for in situ control of the native point defect type and content during growth (see later).

The situation in semiconductor and oxide compound crystals is not nearly as well understood as in silicon. There are still no detailed studies demonstrating the correlation between temperature gradient at the growing interface, crystallization rate, and content of the given intrinsic defect types. Of course, one reason is the presence of dislocations acting as effective getters (Sect. 6.3) that make it difficult to study the point defect dynamics in the pure form. In principle, as demonstrated in (6.5), the situation in multicomponent materials is additionally complicated due to the presence of equivalent defect types in each sublattice and the formation probability of antisites. It is established that the As_{Ga} antisite in $GaAs$ crystals, known as the neutral $EL2$ defect with charged states $EL2^+$ and $EL2^{2+}$, does not appear at the growth temperature but forms during the cooling-down process. In material grown from a near-congruent composition, i. e., slightly As -rich melt, the As_i content removes the $[V_{Ga}]$ by producing As_{Ga} as soon as the lowering temperature evokes supersaturation [6.33]. A nearly identical mechanism takes place in $CdTe$. In cooling Te -saturated samples the antisite Te_{Cd} does form and may become important as singly and doubly ionized mid-gap donors $Te_{Cd}^{1+,2+}$ responsible for compensation of the shallow native acceptor $V_{Cd}^{1-,2-}$ [6.36].

For understanding the defect trapping kinetics at a propagating melt–solid interface, first of all one has to clarify whether the front moves by atomically rough or smooth morphology. This can be estimated by the Jackson factor [6.37] $\alpha = (w/u)\Delta H/k_B T$, where ΔH is the enthalpy of crystallization, w is the number of nearest neighbors of an atom on the face, u is the number of nearest neighbors of an atom in the crystal, k_B is the Boltzmann constant, and T is absolute temperature (see also Sect. 6.5). Whereas metals show α values of about 1, i. e., a rough interface, dielectrics crystallize mostly with atomically smooth interfaces due to typical α values larger than 2. In between stand the semiconductor materials with their covalent bondings and, hence, α factors around 2. In this case the crystallographic binding structure along the crystallizing plane (w/u) determines whether the interface is microscopically smooth or rough. Semiconductors with diamond,

Fig. 6.3 Sketch of intrinsic point defect kinetics of an AB compound at an atomically flat melt–solid interface propagating by step-growth mechanism (R_{st} – lateral step-growth rate)

zincblende, and wurtzite structures grow from the melt along most directions by the atomically rough mode. They tend to form atomically smooth interfaces only on their most close-packed (i. e., $\{111\}$) planes (see also Sect. 6.5).

On atomically rough interfaces atoms can be added singly without the need for nucleation, i. e., at very low chemical potential difference between solid and liquid phases. As a result, possible defect sites are added to the crystal under quasi-equilibrium conditions. On the contrary, for atomically smooth planes much higher supercooling is required in order to initiate two-dimensional (2-D) nucleation followed by layer-by-layer growth. In such a case vacancies, interstitials and even foreign atoms, possibly delivered by the adjacent liquid boundary layer, can be overgrown very rapidly and, hence, incorporated in metastable states if their diffusion rate back to the melt is not high enough. The sketch in Fig. 6.3 demonstrates this situation. According to *Chernov* [6.38] equilibrium incorporation takes place only when the lateral step rate R_{st} fulfils the inequality

$$R_{st} < \frac{D_{IF}}{h}, \quad (6.6)$$

where D_{IF} is the interface diffusion coefficient (10^{-4} – 10^{-5} cm^2/s) and h is the step height. The actual step growth velocity can be estimated by the relation

$$R_{st} = \beta_i \Delta T, \quad (6.7)$$

where β_i is the kinetic step coefficient [6.38,39], which for silicon is 50 cm/(s K) [6.40], and ΔT is the supercooling, which has been determined at growing {111} facets of silicon crystals to be a maximum of 7 K [6.41]. Hence, at very high step flow rates, i. e., relatively high supercooling, nonequilibrium (metastable) point-defect incorporation can result.

It seems that the fluid phase should deliver sufficient imperfections due to its structural instability and disordered character. However, as recent MD simulations have demonstrated, between the liquid and crystal surface a characteristic transition region of several atomic layers exists, within which the thermal motion of the atoms decreases and the structure approaches the crystalline one [6.39]. In fact, as was ascertained by high-resolution in situ transmission electron microscopy, the {111} solid-liquid interface of Si has already a well-ordered transition layer on the atomic scale, which is compatible with defect-free 1 × 1 Si-{111} surface [6.42]. It can be assumed that the presence of such an ordered transition region should stabilize the growth kinetics against incorporation of an excess of deficiencies. According to Motooka's MD simulations [6.43], point defects are formed directly at the interface due to the density misfit between the liquid and solid phases.

Point Defect Engineering

In order to ensure specified electrical and optical qualities of single crystals and devices made therefrom the control of native point defects plays an important technological role, especially if harmful secondary reactions are evoked by point imperfections, such as precipitation (Sect. 6.4.1) and microvoid generation. From an experimental point of view, there are two possible ways of defect mastering:

- i) In situ control during the crystal growth process
- ii) Postannealing of the crystal bulk or pieces cut therefrom.

The first method is of increasing interest due to its cost benefits.

In the case of low-dislocation or even dislocation-free crystal growth, the complete native point defect dynamics come into play. The absence of dislocations leads to a quasihomogeneous defect interplay without catalytic effects. As a result the relatively high supersaturation promotes vacancy and/or interstitial condensations within the crystal volume, escalating to unfavorable micro and mesoconglomerations. For instance, in silicon at high pulling rates, vacancies

are incorporated in excess and condense during cooling down to form octahedral voids of ≈ 100 nm. On the other hand, at low pulling rates interstitials are in excess, forming a network of dislocation loops. In between, a defect-free region is obtained which is bounded by unwanted oxidation-induced stacking faults (OSF). The balance between the number of vacancies and interstitials is the controlling factor. Based on these experimental observations three ways to achieve microdefect-free silicon have been worked out [6.35]:

- i) Keeping the growth conditions within the defect-free regime, which is approximately $\pm 10\%$ around the critical ratio $v/G_T = 1.34 \times 10^{-3} \text{ cm}^2/(\text{K min})$, where v is the growth rate and G_T is the temperature gradient at the interface. However, such a small tolerance permits only very low pulling velocities of about 0.5 mm/min. Falster and Voronkov [6.44] described the in situ outdiffusion of interstitials. In this case, the crystals are pulled under interstitial-rich conditions and maintained at high temperatures for extended times, thus utilizing the very high migration speed of interstitials. However, extended cooling times with very low cooling rates are required.
- ii) Keeping a maximum pulling rate with fast cooling followed by a wafer annealing process to reduce the grown-in defect sizes.
- iii) Using a cost-optimized approach, a so-called *flash wafer* step [6.35], where only a thin Si layer of 0.5 μm is deposited onto the wafer surfaces. This combines maximum pull rate and fast cooling with low-cost treatment.

The in situ control of native point defects in compound crystals is coupled with the feasibility of accurate composition control during the growth process and, therefore, with exact knowledge of the phase diagrams. Taking the T - x -phase projections (where x is the mole fraction) one can find numerous AB compounds with a region of homogeneity containing the strict stoichiometric composition and extending to both sides of stoichiometry, such as CdTe and PbTe, for example [6.19]. However, there are also compounds with asymmetric phase extents shifted to anion or cation excess, even not including the stoichiometric composition, such as GeTe and SnTe, for example [6.45]. Also in LiNbO₃ the prevailing part of the existence region is located on the Nb₂O₃-rich side [6.46]. Unfortunately, for a lot of compounds the exact shape and width of the homogeneity region has not yet been clarified, especially when very small phase extents exist, as in InP, InAs,

Fig. 6.4a–c Crystal growth arrangements for in situ stoichiometry control by partial vapor pressure of the volatile element. **(a)** Horizontal Bridgman (HB) method. **(b)** Vertical gradient freeze (VGF) technique. **(c)** Vapor-pressure-controlled Czochralski (VCZ) method ▶

SiC, and PbMoO₄, or if phase relation analysis is difficult, as for ZnO and GaN. Even for GaAs only recently have thermochemical calculations [6.47, 48] confirmed the earlier and newer growth observations [6.49] that the phase extent is deviated exclusively towards the As-rich side. In principle, for materials with phase extents containing or touching the stoichiometric composition, it is obvious from theoretical calculations and annealing studies that stoichiometric growth conditions guarantee a minimum total native point defect concentration.

A method that has been well known for a long time is the in situ control of near-stoichiometric growth by applying a fixed-temperature vapor source of the volatile component in the horizontal Bridgman (HB) method without covering the melt [6.50]. In this technique there is direct contact of the vapor phase with the crystallizing melt–solid phase region, which guarantees near phase equilibrium conditions during the whole growth run (Fig. 6.4a). However, the technical limitation of the HB method for scaled-up production of crystals with diameters larger than 3 inches is commonly known. The vertical Bridgman (VB) and vertical gradient freeze (VGF) techniques have also been introduced, using an extra source for control of the vapor phase [6.51] (Fig. 6.4b). A certain transport transient of the vapor species has to be considered due to the complete covering of the crystallization front by the melt column. As a result the equilibrium temperatures for the vapor pressure source can somewhat differ between the techniques. Vapor-pressure-controlled HB, VB, and VGF have been successfully used to grow near-stoichiometric compound semiconductors, such as CdTe crystals [6.28]. If highly purified material is used even high-resistivity crystals can be obtained [6.52], due to intrinsic defect annihilation and compensation. However, ensuring a highly reproducible, stable intrinsic semi-insulating state over the whole crystal length during the whole growth run is very complicated due to native point defect segregation. A more promising method appears to be compensation doping (Sect. 6.2.2). In general, for VB and VGF, being obviously the most favorable melt growth techniques for semiconductor compounds, stoichiometric processing by in situ vapor pressure control is not yet possible on the industrial scale. The continuously decreasing

height of the melt column and segregation phenomena during the normal freezing process would require a well-controlled source temperature program that is well fitted to the growth rate. As a result, the stoichiometry is still tuned in cut wafers by postgrowth annealing if required for a given application [6.53].

Much less widely practiced is in situ control of stoichiometry in the Czochralski growth of semiconductor compounds. For this a modified technique without boric oxide encapsulant is required to influence the melt composition by the partial pressure of the volatile element. During the 1980s the hot-wall Czochralski (HWC) technique with As (P) source was advanced by Nishizawa et al. [6.54, 55] to analyze the variations of the physical parameters and dislocation density in GaAs and GaP crystals as functions of the melt composition. In recent years in situ control of the stoichiometry in GaAs by vapor-pressure-controlled Czochralski (VCz) technique [6.56] without boric oxide encapsulation has been under investigation [6.49, 57] (Fig. 6.4c). The mole fraction of the melt is controlled in the range of $0.45 \leq x_L \leq 0.50$ by partial arsenic pressures of 0.02–2.1 MPa, adjusted via the temperature of the As source from 540 to 650 °C. The authors [6.57] have demonstrated that near-stoichiometric growth conditions with a Ga-rich melt reduces the As_{Ga} antisite and V_{Ga} concentrations.

To date, for dielectric compounds, Czochralski growth experiments with precise in situ vapor pressure control are still rare. This is first of all due to the much higher growth temperatures and chemical aggressiveness of oxygen or fluorine, which make it difficult and expensive to insert a chemically resistant and gastight inner growth chamber with an extra source. However, some activities have been described. For instance, high-quality composition-controlled $Bi_{12}GeO_{20}$ (BGO) crystals were grown in an inner chamber made of platinum [6.58]. References [6.59, 60] describe a growth arrangement to control the stoichiometry of $PbMoO_4$ crystals with markedly improved optical transmission by using a MoO_3 evaporation source within a bell covering around the pulling crystal. Baumann et al. [6.6] demonstrated the importance of precise melt composition control for the growth of $LiNbO_3$ to obtain crystals with high axial homogeneity of birefringence.

6.2.2 Extrinsic Point Defect Incorporation

Thermodynamics

In growing crystals with dopant concentrations below the solubility limits, the matrix is regarded as con-

tributing one component in a phase diagram and the solute another. Thus, in growing such crystals from the melt, the system can be considered a binary one. The equilibrium between the chemical potentials of added species (i.e., solvent) i in the liquid and solid phases $\mu_{il}(x, T) = \mu_{is}(x, T)$ yields

$$\mu_{is}^0 + k_B T \ln x_{is} \gamma_{is} = \mu_{il}^0 + k_B T \ln x_{il} \gamma_{il}, \quad (6.8)$$

where μ^0 is the standard potential and γ is the interaction activity between i and atoms or molecules of the matrix. Setting $\mu_{il}^0 - \mu_{is}^0 = \Delta\mu_i^0 = \Delta h_i^0 - \Delta s_i^0 T$ and $s_i^0 = h_i^0/T_{mi}$, where h_i^0 and s_B^0 are the intensive standard enthalpy and entropy, respectively, T_{mi} is the melting point of the dopant, and $\Delta h_{Mis,l}^0 = k_B T \ln \gamma_{is,l}$ is the enthalpy of mixing, the transformed equation (6.8) becomes [6.31, 45]

$$\frac{x_{is}}{x_{il}} = k_0 = \exp \left[-\frac{\Delta h_i^0}{k} \left(\frac{1}{T} - \frac{1}{T_{mi}} \right) + \frac{\Delta h_{Mil} - \Delta h_{Mis}}{k_B T} \right], \quad (6.9)$$

where $k_{0i} = x_{is}/x_{il}$ is the (thermodynamic) *equilibrium distribution coefficient*, which can be assumed to be a constant for residual impurity or low dopant concentrations if the solidus and liquidus curves admit linearization. A more exact treatment, however, is provided by the description of the real solidus and liquidus courses by use of regression functions [6.61]. In most phase diagrams the solidus and liquidus courses can be approximated by polynomials. For instance, a polynomial of second order describes the temperature dependence of the solidus and liquidus as $T_{is,l} = p_{is,l} x_{is,l}^2 + q_{is,l} x_{is,l} + T_m$ where p and q are the regression coefficients and T_m is the melting point of the crystal matrix. The concentration dependence of the distribution coefficient then becomes $k_{0i}(x) = (p_{is} x_{is} + q_{is}) / (p_{il} x_{il} + q_{il})$. For the Al–Si system within the temperature region 660 °C (T_{mAl})–577 °C the coefficients are $p_{Sis} = 15.6065$, $q_{Sis} = -77.1694$, $p_{Sil} = -0.0371$, and $q_{Sil} = -6.2958$, for example [6.61].

Much more complicated is the situation of nonstoichiometric compound growth. Usually, the boundaries of the existence regions, being equivalent to the solidus curves of the excess component, show strong nonlinear T, x -behavior. Here a definition of the k_0 value for the given excess component becomes quite difficult, all the more so due to uncertainties in the shape of the phase extent. Such conditions take place during growth of semiconductor compounds. In [6.28, Fig. 4.5]

an attempt was made to estimate the segregation coefficients for Te and Cd in CdTe from the compound solidus courses on the Te- and Cd-rich sides. On the Te-rich side between the liquidus temperatures 1092 and 1080 °C, i. e., from the congruent melting point composition $x_{\text{cmp}} = 0.5 + 5 \times 10^{-6}$ up to a tellurium excess of $\delta x_{\text{Te}} = 5 \times 10^{-5}$, the k_0 value for Te changes between 0.8 and 0.1, respectively.

Interaction with Intrinsic Point Defects

Dopants can become incorporated on lattice sites or interstitial positions. In compounds, depending on their position in the periodic table, dopants may occupy either one or another or even both sublattice sites. In general, their incorporation efficiency is affected by the point defects that are present, which at growth temperatures are isolated and usually electrically charged [6.30]. The charge state of point defects depends on the position of the Fermi level, leading to their complex interaction with electrically active dopants. As a result the dopant solubility can be markedly influenced, and controversially, doping can affect the native point defect solubility.

The incorporation reaction of a dopant from the melt X_I with a neutral vacancy of the B sublattice V_B^0 in a AB semiconductor compound is assumed to be $X_I + V_B^0 = X_B^+ + e$, where X_B^+ is the substituting donor and e is a free electron. If the material is uncompensated the carrier concentration is $n = [X_B^+]$ and the segregation coefficient is

$$k_0 = \frac{[X_B^+]}{[X_I]}, \quad (6.10)$$

being constant as long as the dopant concentration is much lower than the intrinsic content of electron-hole pairs $n_i = [e_i] = [h_i]$ produced by the ionized native point defects. This follows from an effective value of the segregation coefficient k which was derived by *Chernov* [6.38] considering mass balance, electroneutrality, and k_0 from (6.10) as

$$k = \frac{k_0}{\sqrt{1 + \frac{[X_B^+]}{n_i}}} = \frac{k_0}{\sqrt{1 + \frac{[X_B^+]}{n_i}}}. \quad (6.11)$$

As can be seen, when $[X_B^+] \ll n_i$, the value of k equals the equilibrium distribution coefficient k_0 . However, once $[X_B^+]$ rises to $\approx n_i$ the effective segregation coefficient k begins to fall. In other words the dopant efficiency decreases. Physically, this is due to the growing charge state of the intrinsic point defect ($V_B^0 \rightarrow V_B^+ + e$)

in order to preserve the electroneutrality of the crystal $n = (n_i^2/n) + [X_B^+] + [V_B^+]$. This phenomenon has been well known for a long time from numerous melt-grown semiconductor compounds, such as GaAs doped with Te and Si [6.33] and CdTe doped with Ag and Cu [6.62].

The influence of the electron or hole concentration generated by the ionized dopants on the charge state of the native point defects is named the Fermi-level effect [6.63], whereby the degree of ionization depends on the position of the Fermi level [6.24]. For instance, the charge state of the Ga vacancy in GaAs changes from neutral V_{Ga}^0 in p-type material through double negatively charged V_{Ga}^{2-} in the midgap to a triple negatively charged V_{Ga}^{3-} in n-type material, which affects the compensation level and enhances the *complex formation* probability too. An example of a complex reaction in the common form is

as found in the form of $(\text{Te}_{\text{As}} V_{\text{Ga}})^{2-}$ or $(\text{Si}_{\text{Ga}} V_{\text{Ga}})^-$ in GaAs crystals.

Another factor influencing the incorporation efficiency of impurities and dopants is the nonstoichiometry of compounds. The greater the deviation from the stoichiometric composition during growth, the higher the possibility of vacancy generation within the compositionally impoverished sublattice. As a result the incorporation density of atoms at the growing interface occupying these vacant sites increases with nonstoichiometry. This was demonstrated in [6.62], where CdTe crystals were grown by vapor-pressure-controlled Bridgman method (Sect. 6.2.1) from different melt compositions containing Ag, Cu, and P dopants. Whereas Ag and Cu atoms occupy the Cd vacancies when growing proceeds from Te-rich melt, P takes up the Te vacancies on growth from Cd-rich melt. As has been demonstrated, the concentration of the neutral substitutions $[\text{Ag}_{\text{Cd}}^0]$, $[\text{Cu}_{\text{Cd}}^0]$, and $[\text{P}_{\text{Te}}^0]$, determined in as-grown crystal samples by absorption-calibrated photoluminescence [6.64], increased with Te or Cd enrichment of the melt, respectively. Figure 6.5 shows the variation of the substitutional concentration $[\text{Ag}_{\text{Cd}}^0]$ as a function of the starting silver concentration in the melt $[\text{Ag}_I]$ for various tellurium excess. At stoichiometric growth conditions the concentration of Ag_{Cd}^0 is drastically reduced down to $2 \times 10^{13} \text{ cm}^{-3}$. Compared with that, a Te excess of $5 \times 10^{17} \text{ cm}^{-3}$ leads to incorporation of Ag atoms on V_{Cd} sites at about one order of magnitude higher concentration (note the prevailing part of Ag atoms, is incorporated according k_0 in interstitial positions, probably acting as deep donors). The results underline the

Fig. 6.5 Incorporation of silver atoms into substitutional Ag_{Cd} positions in CdTe crystals versus the degree of deviation from stoichiometry (Te excess) of the melt (after Rudolph et al. [6.62])

importance of in situ stoichiometry control in growth of both compound semiconductor crystals and dielectric crystals.

Segregation Phenomena

The redistribution of extrinsic atoms, arbitrarily or deliberately incorporated into a growing crystal, as well as the rearrangement of intrinsic point defects prove to be an essential challenge for the crystal grower. Such phenomena are due to the segregation effect and temperature gradients within the cooling crystal producing chemical and physical crystal inhomogeneities.

The deviation of the equilibrium segregation coefficient (6.9) from unity causes segregation phenomena during melt growth which can be treated in terms of an effective segregation coefficient $k_{\text{eff}} = x_{\text{is}}/x_{\text{il}}^{(\infty)}$, where $x_{\text{il}}^{(\infty)}$ is the mole fraction of the dopant in the melt far away from the interface. During an actual freezing process the solute is rejected ($k_0 < 1$) or preferentially absorbed ($k_0 > 1$) by the propagating solid–liquid interface, forming an enriched or depleted solute boundary layer in front of it.

The width δ_S of this boundary layer is determined by the growth rate R and by the diffusive and convec-

tive species transport in the melt, which is very often difficult to predict. A very popular model which is commonly used in melt growth was introduced by Burton, Prim, and Slichter (BPS) [6.65] for steady-state segregation

$$k_{\text{eff}} = \frac{k_0}{k_0 + (1 - k_0) \exp\left(\frac{-R\delta_S}{D}\right)}. \quad (6.13)$$

The advantage of this model is the ease of its use for plotting experimental data by fitting δ_S . By applying the Cochran flow solution at the surface of an infinite rotating disk, Levich [6.66] obtained the expression $\delta_S \approx 1.6D^{1/3}\nu^{1/6}\omega^{-1/2}$ (where D is the diffusion coefficient in the melt, ν is the kinematic viscosity of melt, and ω is the rotation frequency). Later, Ostrogoriski and Müller [6.67] quantified δ_S more physically for situations where natural convection rather than rotating disc flow dominated by considering its dependence on lateral convection velocity and the length of the interface. They defined $k_{\text{eff}} = (1 + \Lambda)/(1 + \Lambda/k_0)$ where $\Lambda = (v_D\delta_S)/(7.2\nu L)$, v_D is the convective velocity at the edge of the boundary layer, ν is the growth velocity, and L is the length of the interface. The value of k_{eff} is of central importance to explain macro- and microsegregation phenomena.

Macrodistribution

The macrodistribution describes the courses of a given solute concentration over its radius and along the as-grown crystal axis. Whereas the radial rearrangement is first of all affected by the shape of the melt–solid interface, the axial distribution depends on the growth velocity and level of convection in the melt. The degree of segregation depends on the extent to which the solute segregation coefficient (k_0) differs from unity. For instance, an enrichment of the dopants around the crystal center occurs at a concave- or convex-shaped interface and $k_0 < 1$ or > 1 , respectively. Against this, the solute is concentrated near the crystal periphery in the case of a convex interface and $k_0 > 1$. Therefore, only a nearly flat crystallization front can guarantee a homogeneous radial composition distribution.

The axial segregation function for unidirectional solidification in a completely mixed melt is described by the well-known Scheil equation (6.14), being valid for a stable planar crystal–melt interface and conservative mass balance, i. e., no solute evaporation from the melt or recharging into the melt takes place during the whole crystallization process. When the growth process is started with uniform melt concentration x_{i0} , the

concentration in the crystal x_{is} at a distance z from the initial growth face is

$$x_{is} = x_{i0} k_{\text{eff}} \left(\frac{1-z}{L_0} \right)^{k_{\text{eff}}-1}, \quad (6.14)$$

where L_0 is the length of the charge and the process considered is one in which the whole charge is initially molten and then frozen. From (6.13) and (6.14) it follows that k_{eff} equals unity at high growth rates or/and motionless melts, i. e., high values of δ_S in (6.13). In such cases high macroscopic distribution uniformity within the crystal can be reached. However, v is limited by the onset of morphological instability, as shown below. On the other hand, if the melt is stirred, the boundary layer is removed by the melt flow ($\delta_S \rightarrow 0$) and k_{eff} equals k_0 . In this case the axial distribution of the solute is typically inhomogeneous.

In order to obtain high axial chemical homogeneity in modern crystal growth processes often a nonconservative (open) system [6.68] with continuous dopant recharging (or extraction) is applied. This is practiced in the growth of semi-insulating GaAs crystals by applying carbon as a shallow acceptor for compensation of the deep intrinsic donor defects EL2 (As_{Ga}). As follows from (6.14), in the conservative case with complete melt mixing the C distribution, and hence the degree of compensation, which determines the electrical resistivity, becomes decreasing along the crystal axis due to $k_{\text{eff}}^C \approx k_0^C \approx 2$. By contrast, in a nonconservative system the axial distribution can be homogenized by proper in situ control of the CO fugacity within the growth chamber atmosphere delivering the C species for the melt via CO decomposition at the interface between boric oxide encapsulant and Ga-As melt. This is arranged by a controllable CO content within the working gas [6.69], a process well matured on the industrial scale [6.70]. Figure 6.6 compares the axial carbon distribution along GaAs crystals grown under nonconservative doping conditions [6.71]. For such case the Scheil equation (6.14) has to be modified as [6.72]

$$x_{is} = \frac{\eta k_{\text{eff}} x_{iv}}{k_{\text{eff}} + \eta - 1} \times \left(k_{\text{eff}} x_{i0} - \frac{\eta k_0 x_{iv}}{k_{\text{eff}} + \eta - 1} \right) \left(\frac{1-z}{L_0} \right)^{k_{\text{eff}} + \eta - 1}, \quad (6.15)$$

with

$$\eta = \frac{D_{i(\text{B}_2\text{O}_3)}}{h_{\text{B}_2\text{O}_3} v} \left(\frac{r_{\text{cruc}}^2}{r_{\text{cryst}}^2} - 1 \right). \quad (6.16)$$

x_{iv} is the concentration of dopant species in the gas phase at the upper interface of boric oxide, $D_{i(\text{B}_2\text{O}_3)}$ is the transport coefficient of the dopant species in boron oxide ($\approx 5 \times 10^{-8} \text{ cm}^2/\text{s}$ for carbon [6.72]), $h_{\text{B}_2\text{O}_3}$ is the height of the boric oxide encapsulant, and r_{cruc} and r_{cryst} are the radius of the crucible and crystal, respectively.

As is well known, a higher macroscopic homogeneity can be achieved by applying single-pass zone-melt techniques. A relative short first-to-freeze transient is followed by a compositionally uniform level region, the concentration of which equals that of the starting (polycrystalline) source rod, i. e., $x_{is} = x_{i0}$. The axial distribution function is

$$x_s = x_0 \left[1 - (1 - k_{\text{eff}}) \exp \left(\frac{-k_{\text{eff}} z}{L_z} \right) \right], \quad (6.17)$$

with zone length L_z and distance $z < L_0 - L_z$. The final part of solidification when $z > L_0 - L_z$ represents a normal freezing process and the concentration profile is given by (6.14). Single-pass zone growth is successfully used not only for production of extremely highly purified silicon by floating-zone melting [6.73] but also to obtain homogeneous mixed crystals of the

Fig. 6.6 Axial carbon distribution in LEC (\blacktriangle) and VCZ (\bullet) GaAs crystals grown under nonconservative conditions by controlled CO gas concentration (8 mbar) and rinsing nitrogen working gas (≈ 4 bar) [6.56], respectively. The dashed curve shows the theoretical Scheil distribution with $k_0 = 2$ (the equilibrium segregation coefficient of carbon) in case of conservative growth regime with complete melt mixing ($k_0 = k_{\text{eff}}$) and starting concentration $x_{\text{CO}} = 5 \times 10^{14} \text{ cm}^{-3}$

types $A_{1-x}B_x$ or $AB_{1-x}C_x$, even with widely spread liquidus and solidus curves. High-quality $Hg_{1-x}Cd_xTe$ and $Cd_{1-x}Zn_xTe$ crystals with axial uniformity of the constituents can be grown by the traveling-heater method (THM) from a Te-rich zone [6.74, 75]. Uniform oxide mixed crystals have been grown by a special heater-immersed zone melting technique [6.76]. Another use is microzone melting for the growth of various oxide fiber crystals by laser-heated pedestal growth (LHPG) [6.77]. Today this technique is applied for the production of nearly preparation-free microlasers for wavelength conservation by higher-harmonic generation [6.78].

Microinhomogeneities (Striations)

Microinhomogeneities are short-range composition fluctuations with characteristic spacing ranging from $1\text{ }\mu\text{m}$ to 1 mm , usually modulating the macrodistribution as *fine structure*. Such oscillations are found in nearly all crystals and are visible under light microscopy as *striations* on crystal cuts, especially after etching (Fig. 6.7a,b). They are one of the most investigated crystal defects [6.2, 3], and can seriously limit the device application of the given crystal (Sect. 6.1). Nonuniform segregation of solutes on the microscale is due to a variety of mechanisms, as recently summarized by Scheel [6.80]. Principally, one has to differentiate between kinetically and thermally induced striations.

Kinetic striations appear in the discontinuous (step-by-step) growth mode of atomically flat interfaces or facets (Sect. 6.5) when macrosteps are formed by bunching. Their repeated rapid lateral growth tends to trap the adjacent solute in alternating nonequilibrium concentration. At misoriented growth planes the propagation direction of the macrosteps, and hence striations, are inclined to the macroscopic course of the interface. This phenomenon is well known from liquid phase epitaxy (LPE) experiments [6.81].

Thermally induced striations are generated by non-steady growth velocities $\Delta v/v$, leading to variation of k_{eff} (6.13). Oscillating interface rates are caused by temperature fluctuations, which can be induced by:

- i) Rotation of Czochralski crystals in thermally asymmetric melts [6.82]
- ii) Convective instabilities [6.45, 67].

Vibrations and pressure fluctuations have also been identified as sources of growth rate variations. After Hurle's treatment [6.83], for certain frequencies of temperature oscillation, resonant coupling should occur between thermal and solute fields to give large compositional amplitudes.

For low-frequency oscillations with fluctuation periods $\tau > 2\delta_S/D$ (longer than about 10 s) the concentration changes are associated with growth rate R changes

Fig. 6.7a,b Striations in semiconductor crystals. **(a)** Section of Te-doped InSb crystal grown in the presence of thermal oscillations in the melt [6.79] (after [6.45]; reproduced by permission of Springer). **(b)** Section of an undoped VCZ GaAs crystal grown from incongruent As-rich melt with compositional striations marking the interface shape. The arrows show the trace of a dislocation bundle propagating perpendicularly to the interface (courtesy of U. Juda from IKZ Berlin)

according to the steady-state BPS relation (6.13)

$$\begin{aligned} \frac{\Delta x_{is}}{x_{is}} &= \frac{\Delta R}{k_{\text{eff}}} \frac{\partial k_{\text{eff}}}{\partial R} \\ &= \frac{\Delta R}{R} \frac{(1-k_0) \left(\frac{R\delta_s}{D} \right) \exp\left(\frac{-R\delta_s}{D}\right)}{k_0 + (1-k_0) \exp\left(\frac{-R\delta_s}{D}\right)}. \end{aligned} \quad (6.18)$$

The maximum composition amplitude $[(\Delta x_{is}/x_{is})/(\Delta R/R)]_{\text{max}} = (1-k_0)(R\delta_s/D)$ occurs under conditions where $R\delta_s/D \ll 1$. By contrast, for high-frequency growth rate oscillations ($\tau < 2\delta_s/D$), the reaction time of the mass diffusivity is no longer able to follow the thermal agility. Thus, the amplitudes of the compositional fluctuations are increasingly reduced with increasing perturbation frequency f as

$$\frac{\Delta x_{is}}{x_{is}} = \frac{\Delta R}{R} (1-k_0) \frac{\frac{R\delta_s}{D}}{\left(\frac{2f\delta_s^2}{D}\right)^{1/2}}. \quad (6.19)$$

At frequencies higher than 10 Hz the relative concentration fluctuations fall to less than 10%. Therefore, low-frequency fluctuations affect the crystal homogeneity much more than do high-frequency ones. In other words, a melt–solid interface acts as a *low-pass filter*. Unfortunately, in crystal growth melts convective frequencies in the range of $0.1\text{--}0.5\text{ s}^{-1}$ are typical and the relation (6.18) must be used.

There are two general ways to damp temperature oscillations within the melt (when growth under microgravity is not considered):

- i) Brake the buoyancy convection streams
- ii) Minimize the temperature differences.

For the first method the application of various kinds of magnetic fields proves to be very effective for melts with electrical conductivity [6.84]. In the second case measures for temperature homogenization by using high-frequency melt mixing are required. From the above discussion, it follows that they are not dangerous for crystal homogeneity. Appropriate techniques are the accelerated crucible rotation technique (ACRT) [6.85] and ultrasonic vibration stirring [6.86].

Note that, for fundamental research and technology developments, the presence of striations proves to be of certain advantage because of their ability to mark the interface shape. Striation analysis along longitudinal crystal cuts reveals the time and course characteristics of the crystallization front during the whole growth process. Note that striations appear even in high-purity compound crystals grown from slightly

off-congruent melting point composition. For instance, in standard semi-insulating GaAs crystals grown from slightly As-rich melts, striations of very small and harmless amplitudes can be resolved by use of diluted Sirtl with light (DSL) etching [6.87] (Fig. 6.7b). They reflect the alternating incorporation of As-related native point defects [6.88]. For some materials it is important to consider the relatively high diffusion coefficients in the solid, leading to a leveling effect [6.89]. For instance, in melt-grown (Hg,Cd)Te mixed crystals, striations are not revealable due to the extremely high D_s^{Hg} .

6.2.3 Constitutional Supercooling – Morphological Instability

Under certain conditions, especially if the melt is not mixed by convection or stirring (i.e., if the solution boundary layer δ_s is well developed), the interface can become morphologically unstable. Both an enriched ($k_0 < 1$) or depleted ($k_0 > 1$) solute layer δ_s , showing a typically exponential concentration course (increasing or decreasing, respectively) at the growing interface, give rise to constitutional instability, especially if the corresponding liquidus temperatures of the concentration course exceed the actual temperature course

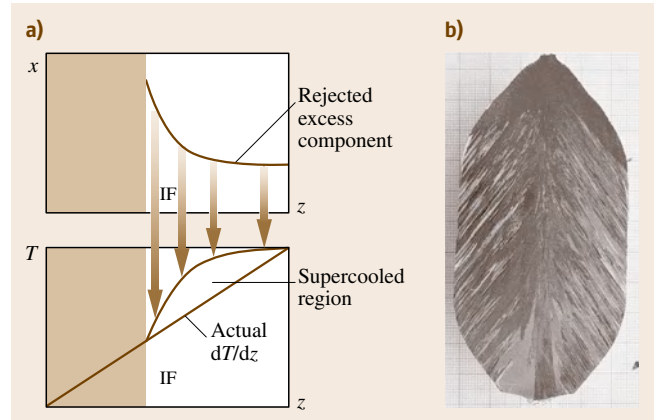

Fig. 6.8a,b Constitutional supercooling of the growing melt–solid interface. (a) Sketch demonstrating the supercooling effect at the interface due to the rejection of impurity, dopant or excess component (above x – z diagram) that leads to higher equilibrium melt temperature distribution compared with the actual temperature gradient (below T – z diagram; x – concentration, T – temperature, z – axial direction). (b) Undoped LEC InP crystal with features of morphological instability (cellular interface) grown from In-rich melt with too high a pulling rate (courtesy of M. Neubert and A. Kwasniewski from IKZ Berlin)

(Fig. 6.8a). Then random formation of a projection on the interface advances that portion of the interface into the region of increased supercooling, where it can grow more rapidly, causing lateral segregation of solute that suppresses growth in the neighboring region. As a result a close-packed array of such projections is formed on the length scale of the lateral diffusion distance D/ν . Such cellular interface morphology produces harmful columnar grain boundary structures with redistributed concentration and dislocation densities leading, finally, to polycrystallinity (Fig. 6.8b). This is exactly what happens in most metal alloy systems [6.90].

For semiconductors, however, faceted interfaces can be obtained. Once the amplitude of the projections grows to the point that their interface with the melt becomes tangential to a {111} faceting direction (Sect. 6.5), microfacets form on the interface [6.2, 3]. This occurs even if the dopant is not the cause of the constitutional supercooling. A noncongruent melt produces rejection of the component in excess and this lowers the liquidus temperature in exactly the same way as a solute. Because of the development of microfacets, the morphology of the resulting cellular structure is orientation dependent (not to be confused with the polygonized cell structure described in Sect. 6.3.2). In principle, dielectric (oxide) crystals that grow under conditions of constitutional supercooling always show faceted interfaces due to their atomically smooth interface kinetics on all important crystallographic planes.

First, Tiller et al. [6.91] deduced theoretically the condition for prevention of constitutional supercooling (i. e., preservation of morphological stability of the interface) as

$$\frac{G}{R} = \frac{m x_{il}(1 - k_0)}{k_0 D}, \quad (6.20)$$

where G is the temperature gradient in the melt at the interface and m the slope of the liquidus from the T - x -phase diagram projection (all other parameters are introduced above). Of course, relation (6.20) is an approximation that ignores some stabilizing factors. In particular, a face growing by an atomically flat mechanism is more stable against disturbances [6.38]. Further, the convection can stabilize the interface morphology by effective removal of the solute layer. Indeed, the

application of artificial melt mixing techniques, such as ACRT [6.85], ultrasonic vibration stirring [6.86] or time-dependent (i. e., rotating, alternating, traveling) magnetic fields [6.92–94], can help to ensure morphological stability very effectively.

A linear stability analysis predicting the exact conditions of onset of the morphological instability was later developed by Mullins and Sekerka [6.95], completing equation (6.20) by consideration of the heat diffusivity in the melt and solid. In subsequent years the theory was widely extended to include higher-order bifurcations and additional physical effects such as melt flow, atomic kinetics, Soret diffusion, applied electric fields, etc. All treatments showed that the Tiller criterion (6.20) can serve as a good approximation for the crystal grower. A detailed review is given in [6.96].

Constitutional supercooling can also appear during growth of undoped compound crystals growing from noncongruent melts. As shown above, in such cases the equilibrium segregation coefficient k_0 cannot be assumed to be constant. Wenzl et al. [6.97] modified the Tiller criterion (6.20), replacing the liquidus–solidus relation with the difference between the congruent melting composition x_{cmp} and the deviation from it in the melt x_1 . When x_{cmp} is close to the stoichiometric composition, as can be assumed for most compounds, one can set $x_{\text{cmp}} \approx 0.5$ and the undercritical growth velocity becomes [6.97]

$$R \leq \frac{GD}{(0.5 - x_1)} \left(\frac{dT}{dy} \right)^{-1}, \quad (6.21)$$

where D is here the diffusion coefficient of the excess component in the melt and dT/dy is the slope of the liquidus at the given x_1 . Obviously, R can be chosen relatively large close to the congruent melting point ($dT/dy \approx 0$). However, it falls drastically with increasing deviation and becomes for GaAs at $x_1 = 0.55$ (i. e., 5 at. % As excess, $D \approx 10^{-5} \text{ cm}^2/\text{s}$, $dT/dy \approx -200 \text{ K}$ [6.97]) about 4 mm/h, being markedly lower than the growth rate of standard crystals growing from near-stoichiometric melt composition. Figure 6.8b shows an image from the longitudinal cut of an InP crystal grown with overcritical growth velocity from an In-rich melt. The polycrystalline columnar structure induced by morphological instability is quite perceptible.

6.3 Dislocations

Contrary to native point defects (Sect. 6.2), dislocations are not in thermodynamic equilibrium, and hence in

principle are preventable. However, at present only silicon and germanium standard crystals can be grown

dislocation-free. This is because in compound crystals the situation is complicated by much higher intrinsic point defect content and lower critical resolved shear stress τ_{CRSS} (e.g., in GaAs and CdTe near the melting point, ≈ 0.5 MPa instead of ≈ 10 MPa in Si) markedly increasing the dislocation mobility and multiplication probability.

Dislocations in a growing crystal which come from the seed are termed grown-in dislocations. In the course of crystal cooling within a given temperature field the development of the dislocation density correlates closely with the thermomechanical stress induced by temperature nonlinearities within the crystal volume. It is the aim of dislocation engineering to achieve uniaxial low thermal gradients in order to minimize the elastic stress, and hence the dislocation density. To achieve this computational modeling of nonstationary plastic deformation proceeding within the crystal is today absolutely essential.

The phenomenon of dislocations interacting with each other at high temperatures is driven by mutual screening of the individual energetic fields and also by dissipative ordering processes in the framework of nonequilibrium thermodynamics. These processes, described by the principles of dislocation dynamics (DD), lead to characteristic collective rearrangements into cell patterns, bundles, and lineages. It can be shown experimentally that the cell size correlates with the mean dislocation density and acting elastic stress. Depending on material parameters, stress value, and the ripening level of dynamic polygonization, the cells transform into low-angle grain boundaries. Dislocation cells and bundles are not observed under low linear temperature gradients, stoichiometric growth conditions, and nearly flat interfaces. See also Chap. 4 in the present Handbook.

6.3.1 Dislocation Types and Analysis

Dislocations are linear crystallographic defects, or irregularities, within a crystal structure. Such linear defects cannot start or end within the crystal. They enter or leave the crystal through its surfaces, with the exception of dislocation loops closed within the crystal volume. The presence of dislocations strongly influences many of the properties of materials (Sect. 6.1) because of lattice distortion, local stress field, electrical activity, and getter ability for point defects. As defined by the angle between the dislocation line and the Burgers vector there are two primary dislocation types: *edge dislocations* and *screw dislocations* with an angle of 90° and 0° , respectively. *Mixed disloca-*

tions are intermediate combinations between these. In the diamond and zincblende structure 30° and 60° dislocations appear within the $\{111\}$ planes with Burgers vector $\mathbf{b} = a_0/\sqrt{2}$ along the $\langle 110 \rangle$ directions (a_0 = lattice constant). In semiconductor A^{III}–B^V compounds 60° dislocations are the prevailing ones, amounting in GaAs to 30% of all dislocation types present [6.98].

It is experimentally and theoretically well established that, independent of the growth method, the density and distribution of dislocations in melt-grown crystals are due to a thermoplastic relaxation of thermally, and to a much lower extent constitutionally, induced stress during growth. Principally, for growing crystals a differentiation between the terms *generation* and *multiplication* of dislocations is recommended. The formation of new dislocations within an ideal dislocation-free crystal under normal growth conditions is nearly impossible. Stresses of the order of the material strength limit $\tau \approx 10^{-2} - 10^{-1} G$ (where G is the shear modulus $\approx 10 - 70$ GPa) would be required, being much higher than that usually obtained in standard growth processes (around 10 MPa at most). Such values are not even high enough to penetrate Shockley partials in zincblende structures from microscopically stepped crystal surfaces, which requires stresses of at least ≈ 100 MPa [6.99]. Dislocations can be generated in the form of Frank loops due to collapsing vacancy agglomerations, interstitial disks, and interface misfits between foreign-phase inclusions and matrix (Fig. 6.1). The possibility of such origins is enhanced in nonstoichiometric material. The majority of dislocations in as-grown crystals, however, originate from glide- and climb-assisted elongation (bowing out) and multiplication (dissociation, cross-glide) of primary existing faults grown-in from the seed crystal.

There exist numerous reliable methods to analyze dislocations such as:

- i) High-resolution transmission electron microscopy (HRTEM)
- ii) X-ray Lang topography, enabling Burgers vector analysis
- iii) Laser scattering tomography (LST), ascertaining the spatial dislocation courses
- iv) Fully automatized etch pit density (EPD) mapping.

Even high-temperature synchrotron x-ray and transmission electron imaging techniques make it possible to study the dislocation kinetics at the crystallization front of some materials in situ [6.100]. As a result, knowledge about dislocation types and their mobility in correlation with the growth conditions as well as their

interaction with dopants is today well developed and a large number of related papers are available. For III–V compounds, a comprehensive summary was published by Sumino and Yonenaga [6.101], for example.

6.3.2 Dislocation Dynamics

Basic Considerations

Dislocations are the elementary carriers of plastic flow, relaxing the elastic stress, which affects the crystal structure. Plastic relaxation (i. e., deformation) of crystalline solids is related to the motion and multiplication of dislocations. This is a basic process within growing crystals by which dislocations are stored. The study of propagation and interaction of dislocations over mesoscopic distances is the subject of dislocation dynamics [6.102]. Because the collective behavior of dislocations is complicated, to date very little is known about the effects that individual dislocations have on each other when they come into close proximity, and more generally about the evolution of collections of strongly interacting dislocations near the melting point. In this chapter basic processes and some characteristic features of dislocation rearrangements into cells and bundles during crystal growth from the melt will be presented.

Dislocations can move within the glide plane by *glide* or *slip* in the direction of b (edge dislocations) or orthogonal to b (screw dislocation) or at a certain angle (30° and 60° dislocations). In addition, screw dislocation can *cross-slip* from one glide plane to another. *Climb* is the motion of dislocations perpendicular to the glide plane. Note that even climb and cross glide are responsible for spatial dislocation (see below).

The glide mobility v_g is given by

$$v_g = v_0 \tau_{\text{eff}}^m \exp\left(-\frac{E_a}{k_B T}\right), \quad (6.22)$$

where v_0 is the material constant, of the order of the magnitude of the Debye frequency, E_a is the activation energy (Peierls potential), $\tau_{\text{eff}} = \tau - A\sqrt{\rho_0}$ is the effective shear stress on dislocations, m is the stress exponent, τ is the acting shear stress, $A = Gb/2\pi(1-\nu)$ is the strain hardening factor, G is the shear modulus, ν is Poisson's ratio, and ρ_0 is the mobile dislocation density.

Usually, at higher temperatures, the process of climb constitutes the dominant mode of dislocation motion. It is thermally activated and therefore dependent upon the diffusivity of vacancies or interstitials to the dislocation core. A phenomenological expression for dislocation

climb velocity v_{cl} is given by [6.103]

$$v_{cl} = B \left(\frac{D_s}{b}\right) \left(\frac{G\Omega}{k_B T}\right) C_j \left(\frac{\gamma_{\text{SF}}}{Gb}\right)^2 \left(\frac{\tau}{G}\right), \quad (6.23)$$

where B is a constant on the order of 10^3 , Ω is the atomic volume, C_j is the concentration of jogs, and γ_{SF} is the stacking fault energy (all other parameters are introduced under relation (6.22)).

The cross-slip mechanism can proceed effectively only in case of relatively high stacking fault energy. Even in semiconductor compounds with zincblende structure containing characteristic partial dislocations (Shockley partials), cross-slip can be restrained due to a large equilibrium stacking fault distance between them, inversely related to the stacking fault energy γ_{SF} as $d_{\text{Sh}} = Ga_0^2/(24\pi\gamma_{\text{SF}})$. InP and CdTe crystals show the lowest stacking fault energies among the semiconductor compounds, and therefore reduced cross-slip probabilities (as a result, dislocation patterning is hindered).

As it is well known the stress force exerted by a dislocation on other dislocations is long range. Moving dislocations tend to minimize their individual stress field by mutual field screening that reduces the overall system energy. There are various mechanisms of dislocation interaction. When two dislocations of opposite Burgers vectors approach each other within a certain critical distance of separation they annihilate. The critical distance for *annihilation* of two screw dislocations is $y_s \approx Gb/2\pi\tau_g$, where τ_g is the shear stress required for dislocation glide. The value of y_s for metals is about 2 μm . However, their approach can also achieve a stable configuration, known as a *dipole*, if the dislocation pair remains both a distance greater than y_s apart and with a relative position angle of around 45°. Typical dipole lengths are on the order of tenths of a micron [6.103]. Dipoles are composed only of edge dislocations since screw dislocations annihilate easily by cross-slip. Furthermore, the attractive forces can lead to the formation of dislocation *junctions* and *walls*. The energy of a dislocation bounded in a stable wall configuration (e.g., a low-angle grain boundary) is about four times lower than the energy of a single dislocation.

Dislocations can multiply by cross-glide and the *Frank–Read mechanism*. In the latter case, multiplication occurs by pinning of the dislocation, bowing out and wrapping around the pinning points. Possible pinning points are precipitates and impurity clusters, but also junction segments produced by two dislocations [6.103]. Nabarro [6.104] discussed the bowing out

by multistep climb under conditions of vacancy supersaturation, known as the *Bardeen–Herring mechanism*.

The above-mentioned mechanisms of dislocation dynamics are considered to be the basic processes taking place during crystal growth from melt under the action of a thermoelastic stress field.

Dislocation Density Versus Thermomechanical Stress

Dislocations in a growing crystal come first of all from the seed (grown-in dislocations), or in special cases from lattice mismatches, e.g., at the interface between the crystal matrix and foreign inclusions, and are multiplied by viscous–plastic phenomena initiated by the thermoelastic stresses experienced by the crystal. Therefore, the content of dislocations is determined by the time- and space-dependent stress level during growth, which is related to the temperature field in the crystal growing and cooling-down procedure. Firstly, *Billig* [6.105] discovered that the dislocation density correlates with the imposed temperature gradient. *Indenbom* [6.106] specified that thermally induced stresses arise from temperature nonlinearity, i. e., divergence of the isotherm curvature from an idealized linear course, in other words not from the temperature profile but from its second derivative. Theoretically, this implies the simplified but quite useful formula

$$\sigma = \alpha_T E L^2 \left(\frac{\partial^2 T}{\partial z^2} \right) \approx \alpha_T E \delta T_{\max}, \quad (6.24)$$

where σ is the thermal stress, α_T is the coefficient of thermal expansion, E is the Young's modulus, L is the characteristic length (about the crystal diameter), T is temperature, z is the given coordinate (pulling axis), and δT_{\max} is the maximum deviation of the isotherm from a linear course. The extremely critical situation in most semiconductor compounds such as GaAs will be obvious by using the material constants near to the melting point ($\alpha_T = 8 \times 10^{-6} \text{ K}^{-1}$, $E = 7.5 \times 10^4 \text{ MPa}$). As can be seen, only very small isotherm deviations from linearity δT_{\max} of 1–2 K are enough to reach the critical-resolved shear stress (CRSS) for dislocation multiplication (0.5 MPa). This is one order of magnitude lower than in silicon, in which much greater isotherm curvatures are tolerated without disturbing dislocation-free growth. Even during pulling of a cylindrical crystal from the melt, steep temperature curvatures can occur due to different temperature gradients in the inner and outer regions of the crystal. From (6.24) follows a direct correlation between stress level and crystal diameter (characteristic length L) which has

been observed in reality. The larger the crystal diameter, the higher the mean dislocation density. For instance, in undoped 3, 4, and 6 inch **LEC** GaAs crystals typical mean dislocation densities are 2×10^4 , 5×10^4 , and $1 \times 10^5 \text{ cm}^{-2}$, respectively.

Modeling of Dislocation Density

From the discussion above it follows that both knowledge and control of the temperature field at all process stages are of essential significance. Due to the difficulties of measurement, numerical simulation is of increasing importance for heat flow, thermomechanical stress, and dislocation density analysis. Two approaches have been used so far [6.7]:

1. Calculation of the thermoelastic stress field (linear theory, isotropic and anisotropic analysis) of the crystal for a given temperature field using available computer packages and comparison of the resolved shear stress (RSS) in the glide systems or the von Mises invariant with the critical resolved shear stress (CRSS), taking into account its temperature dependence known from high-temperature creep experiments. The (local) dislocation density can then be concluded from the total excess shear stress $\sigma_{\text{ex}} = \sum_{i=1}^n \sigma_i^{\text{e}}$ (where n is the number of effective slip systems in the given crystal structure), where $\sigma_i^{\text{e}} = |\sigma_{\text{RSS},i}| - \sigma_{\text{CRSS}}$ for $|\sigma_{\text{RSS},i}| > \sigma_{\text{CRSS}}$ and $\sigma_i^{\text{e}} = 0$ for $|\sigma_{\text{RSS},i}| < \sigma_{\text{CRSS}}$, i. e., the maximum stress at any time of growth determines the local dislocation density. Examples of this approach can be found in *Jordan et al.* [6.107] and *Miyazaki et al.* [6.108].
2. Estimation of the local dislocation density from the constitutive law of Alexander and Haasen linking the relation between plastic shear rate and movement and density of dislocations $d\varepsilon/dt = \rho_0 v b$ (the Orowan equation) with the applied stress in the course of the cooling-down procedure of the crystal [6.109, 110]. The dislocation multiplication is proportional to the effective stress τ_{eff} , the mobile starting dislocation density ρ_0 , and velocity v , i. e., $d\rho/dt = K \tau_{\text{eff}} \rho_0 v$. By using (6.22) the differential equations of state become

$$\frac{d\varepsilon}{dt} = \rho_0 b v_0 \tau_{\text{eff}}^m \exp\left(\frac{E_a}{k_B T}\right), \quad (6.25)$$

$$\frac{d\rho}{dt} = K \rho_0 b v_0 \tau_{\text{eff}}^{m+1} \exp\left(\frac{E_a}{k_B T}\right), \quad (6.26)$$

where K is a multiplication constant (all other values are introduced below (6.22)). A detailed review

of this approach is given by Völkl [6.111]. Lo-honka et al. [6.112] extended this approach to the case of semiconductor compounds with zincblende structure. They considered the different dynamic characteristics of $\alpha(60^\circ)$, $\beta(60^\circ)$ and screw dislocations by modifying the Orowan equation to $d\varepsilon/dt = b(\rho_{0\alpha}v_\alpha + \rho_{0\beta}v_\beta + \rho_{0S}v_S)$. Note that, al-

though only screw dislocations contribute to the total plastic deformation, their dynamics depends also on the motion of $\alpha(60^\circ)$ and $\beta(60^\circ)$ dislocations formed together with screw dislocation loops [6.113], and which therefore have to be considered. Grondet et al. [6.114] included the annihilation of dislocations by pairs, leading to a certain decrease of dislocation density $d\rho^*/dt = d\rho/dt - d\rho^-/dt$ due to its proportionality to the square of the density of dislocation and their velocity: $d\rho^-/dt = A\rho_0^2v^2$ (A is a constant to be fitted by experimental results). This addition leads to a more realistic dislocation density, which becomes overestimated if this effect is neglected.

In general, approach 2 is the modern and more realistic way. As emphasized by Völkl [6.111], the plastic relaxation varies due to time-dependent experimental conditions and due to continuously acting dislocation dynamics. Therefore, the driving force for dislocation multiplication is given by the actual value of the elastic strain and not by the total deformation. Thus, one has to consider that the often-published *von Mises contours* (as part of approach 1), calculated along growing crystal cuts and cross-sections, reflect snapshots of the unrelaxed thermoelastic stress only. Certainly, they are usable for estimation of the dislocation density at the growing interface but not within the cooling crystal volume where the majority of the elastic strain is already relaxed by plastic deformation. Note that changing stress situations can appear during the growth run, as in the LEC case when the crystal emergences from the liquid encapsulant towards the streaming gas atmosphere, creating a thermoelastic shock, for example.

Recently Pendurti et al. [6.115] reported the global numeric modeling of the nonstationary elastic stress and related dislocation development in growing LEC InP crystals by considering the history of the thermal field in the furnace and crystal as well as the convection in the melt and vapor phase. Figure 6.9 shows their calculated elastic stress history and related dislocation density evolution at two selected crystal points.

Fig. 6.9 The history of elastic stress and dislocation density at the edge (1) and in the center (2) of a 2 inch InP crystal growing from the melt under a 20 mm-thick B_2O_3 layer (sketch at the bottom) calculated by a broadened Haasen–Alexander model with Grashof numbers of gas and melt of 10^8 and 10^6 , respectively, and rotational Reynolds number of 500 (after Pendurti et al. [6.115]) ◀

As the elastic stress alternates, the dislocation density increases stepwise accordingly. The authors found that gas convection has a significant effect on the total dislocation density – a quite important fact that had not yet been considered.

The modeling of thermoelastic stress fields and the related dislocation density during a crystal growth process based on constitutive principles of continuum mechanics has made marked progress during the last decade. For both semiconductor compounds [6.114, 115] and oxides [6.116] the comparison between the theoretical results and real structural quality (i. e., mean EPD distributions) along the growth axis and radius show good conformities. However, even today one is still unable to predict exactly the dislocation rearrangements in characteristic microstructures, such as cell patterns and dislocation lineages and bundles, observed in most as-grown crystals under evolving thermomechanical stresses (see below). There are numerous efforts to simulate correctly the three-dimensional dislocation dynamics representing the collective interaction processes [6.117]. However, because of the high computational cost of discrete simulations, present-day modeling is restricted to metals and small system sizes (typically about $10\mu\text{m}^3$) so that only the very first stages of dislocation cell patterning can be studied. Since the cell size of the incipient dislocation cell patterns is of the same order as the size of the simulation box, not much information about the spatial morphology of the emergent patterns can be obtained. Hence, further theoretical methods such as continuum and stochastic approaches are under current development [6.117].

Dislocation Patterning

During plastic relaxation the interacting dislocation populations tend to rearrange spontaneously into characteristic heterogeneous formations. They can be subdivided into two basic patterning phenomena observed in numerous as-grown crystals, i. e.:

- i) Dislocation *cell structuring*
- ii) Dislocation *bunching*.

In compounds and alloys, patterning leads to physical and chemical parameter inhomogeneities. Whereas (i) includes formations of three-dimensionally ordered honeycomb-like (often named mosaic) structures, group (ii) compiles local accumulations such as slightly wavy dislocation walls (lineages) and vein-like bundles and gnarls. Today, dislocation theory can explain the prop-

erties of individual dislocations reasonably well, but is still unable to solve their collective behavior in all its details [6.118]. Hence, the following sections will concentrate on some typical features and practical relationships only. For more theoretical understanding the recently published reviews [6.117, 119] are recommended.

Cellular Structuring

The self-rearrangement of dislocations present in cellular networks during single-crystal growth is typical of most substances used. Figure 6.10a shows such cells in a 4 inch GaAs wafer, revealed by a standard etching process. The cell structure can be analyzed in more detail by laser scattering tomography (LST), which takes advantage of dislocation decoration by precipitates of the excess component in the case of nonstoichiometric crystals [6.120] (Fig. 6.10b), or by high-resolution x-ray synchrotron topography (ST) [6.121] (Fig. 6.10c).

The cells are of globular-like shape, consisting of walls with high dislocation density separated by interiors of markedly dislocation-reduced or even dislocation-free material. Their size decreases with increasing average dislocation density, yielding diameters of 1–2 mm and $500\mu\text{m}$ at dislocation densities of $\rho \leq 10^4$ and $\approx 10^5\text{ cm}^{-2}$, respectively. Note that they are often termed mosaic structures due to their appearance in two-dimensional cuts. Such patterns are also well known from as-grown crystalline metals (e.g., Fe, Al, Ni, Mo), metallic alloys (e.g., Fe-Si, Ti_3Al , Cu-Mn), and dielectric crystals (e.g., LiF, CaF_2 , SrTiO_3 , quartz) [6.122]. However, some differing morphological details are noteworthy. For instance, in Mo, Cu-Mn, and GaAs the cell interiors are nearly free of dislocations and the walls are fuzzy and of certain thickness, consisting of many tangled dislocations (Fig. 6.10c). It is noteworthy that the tilt angle between the cells in high-quality GaAs standard crystals is around 10 arcs. Compared with that in CdTe, PbTe, and CaF_2 the mean disorientation angle is higher (> 20 arcs up to some arcmin) and the cell walls are very thin, of the order of one dislocation row, resembling classical low-angle grain boundaries. In these crystals the matrix shows mostly individual dislocations that can occasionally form a sub-cell structure. Finally, there are crystals in which cell structures are not well distinguishable in the as-grown state, as in InP, or even missing if special dopants are added, as for Si in GaAs or Se in CdTe [6.122]. After Rudolph [6.122] the most probable reasons for missing cell structures are:

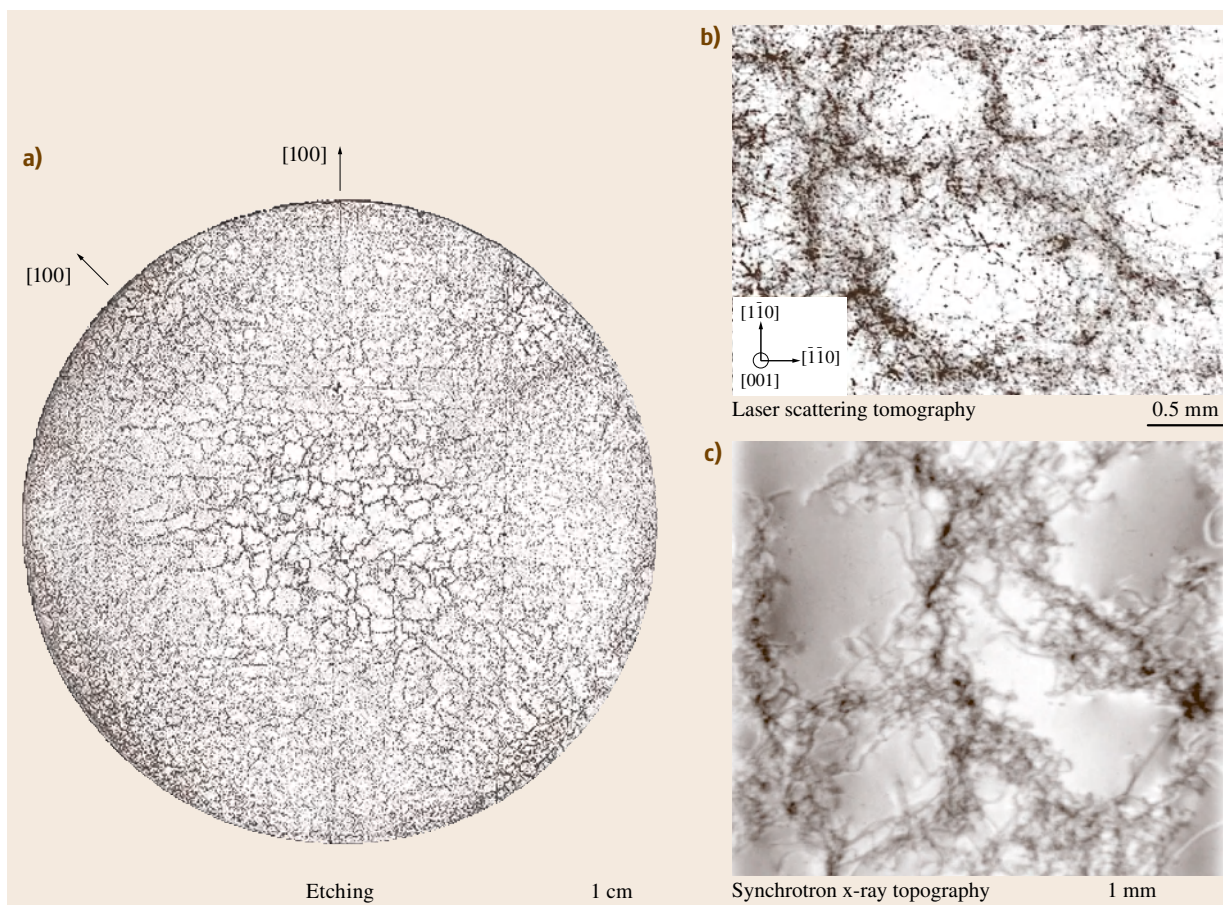

Fig. 6.10a–c Dislocation cell structures in GaAs crystals. **(a)** KOH-etched 4 inch wafer of a VGF crystal (after [6.56]). **(b)** LST analysis with integrated depth 2 mm (after [6.120]). **(c)** X-ray synchrotron topography (after [6.121, 122]) (reproduced by permission of Elsevier **(a,b)** and Wiley-VCH **(c)**)

- i) Low stacking fault energy preventing cross-slip
- ii) Small compound existence regions or stoichiometric growth conditions delivering only low native point-defect reservoir for climb
- iii) Retarded dislocation movement
- iv) Solution hardening by doping.

Undoped InP meets (i–iii). A possible explanation for the markedly differing wall morphologies in the cell structures in as-grown crystals is the different ripening levels within the framework of polygonization. Obviously, in Cu and GaAs the high tendency for dislocation screening by pronounced sessile junction formation leads to an entangled dislocation jungle within the walls being even stable against postannealing. Such mor-

phology resembles the so-called incidental dislocation boundaries (IDBs), which are assumed to be a result of statistical mutual trapping of dislocations. On the other hand CdTe, PbTe, and CaF₂ show typical characteristics of well-ripened low-angle grain boundaries, i.e., geometrically necessary boundaries (GNBs) [6.123].

Cell patterning is studied best in metals under an external load, but also in postdeformed elemental and semiconductor compound crystals. Today, there are a large number of papers dealing with cell patternings, especially in the field of metal physics and mechanics. For growing crystals, however, there is not yet detailed knowledge about the genesis of DD at high temperatures. In all probability, cellular substructures are due to the action of the internal thermomechanical stress field.

It can be assumed that cell formation is coupled with dynamic polygonization behind the growing interface where the plastic relaxation by dislocation multiplication takes place. There is a well-confirmed in situ observation on thin crystallizing and remelting Al plates by *Grange et al.* [6.124], who observed by real-time synchrotron x-ray topography that the cellular dislocation structure appears due to the thermally induced strain within the region already some millimeters behind the melt–solid phase boundary. Recently, *Jakobson et al.* [6.125] confirmed such fast dynamics by in situ x-ray reflection analysis on deforming Cu crystals. The observation strongly indicated that subgrain formation is initiated shortly after the onset of plastic deformation. This result is of great importance for understanding cell genesis in growing crystals, whereupon the cell pattern in the cooled crystal can be assumed to be identical to the structure formed under high temperatures, and is therefore generated by the initially acting thermoelastic stress.

Note that not all types of patterning can be attributed to DD that takes place within the crystal volume. As discussed in Sect. 6.2.3, in the case of morphological instability of a fluid–solid phase boundary induced by constitutional supercooling, the former planar shape changes into a characteristic cellular profile [6.90, 96]. As a result, a lamellar-like structure with longitudinally extended walls is formed. However, the distinction from dislocation patterning is sometimes not trivial, even when cross-sectional crystal wafers are investigated. The best way to distinguish between them is the application of analytical methods with three-dimensional (3-D) imaging such as LST to reveal the globular cell morphology typical of dislocation patterning [6.120]. Moreover, as is well known, dislocation cells may disappear completely if certain dopants are added, such as In in GaAs or Se in CdTe, although their presence could promote constitutional supercooling.

A systematic analysis of the origins and genesis of cell formation during growth of semiconductor compound crystals, especially GaAs, was started by *Rudolph et al.* [6.20, 126, 129]. First, the relation between the stored dislocation density ρ and the cell size (diameter) d has been determined. To deduce the 3-D cell diameters from the 2-D etch pit images obtained on cut wafers, a stereological analysis method was used, as described in [6.126]. Figure 6.11a shows this correlation taken from experimental data. The literature data of deformed metals are added [6.127]. For the GaAs samples with $\text{EPD} \geq 10^4 \text{ cm}^{-2}$ nearly the same correlation as in

deformed metals has been found, i. e.,

$$d \approx K \rho^{-1/2}, \quad (6.27)$$

with the factor of proportionality $K \approx 10\text{--}20$. This is surprising if one considers the marked differences between dislocation densities and cell dimensions in as-grown GaAs crystals and those in metals under load. The result shows that *Holt's* scaling relation [6.127] is

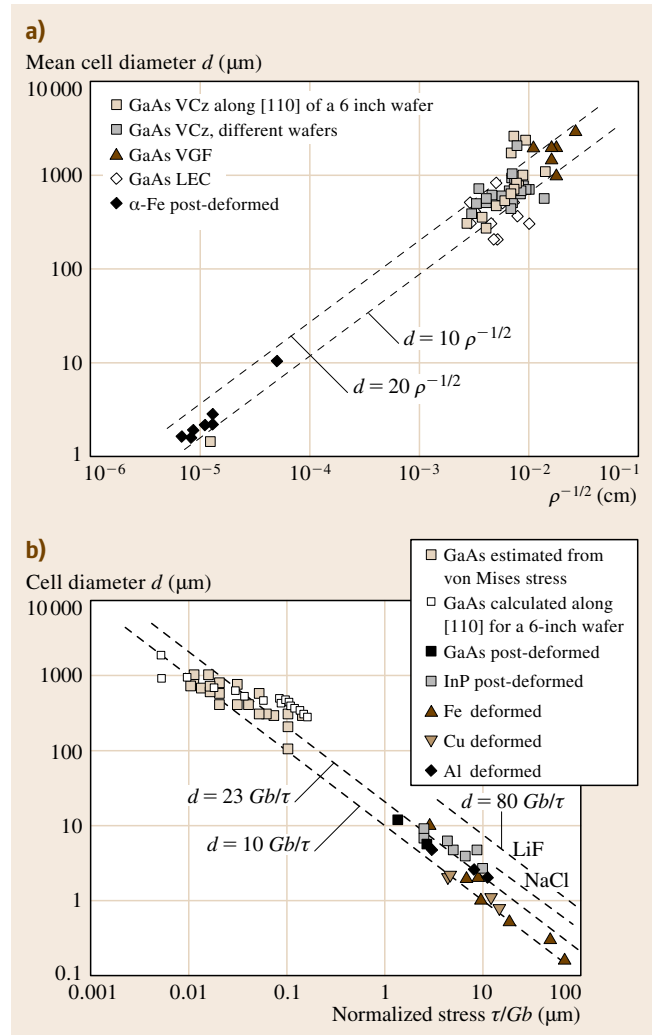

Fig. 6.11a,b Scaling of dislocation cell patterns in growing GaAs crystals in comparison with other crystalline materials post-deformed by mechanical stress (after [6.122, 126–128]). (a) Cell size d versus mean dislocation spacing $\rho^{-1/2}$, i. e., dislocation density ρ . (b) Cell size d versus flow stress τ (reproduced by permission of Wiley-VCH)

fulfilled over a wide range of materials and dislocation densities. At dislocation densities below $5 \times 10^3 \text{ cm}^{-2}$, however, the cells begin to dissociate.

Furthermore, the relation between acting stress and cell dimension was investigated. From postgrowth deformation experiments on numerous metals and dielectrics a universal relation between cell diameter and shear stress τ was found [6.130]:

$$d = \alpha K G b \tau^{-1}, \quad (6.28)$$

where α is another proportionality factor, G is the Young's shear modulus, and b is the Burgers vector. The analysis of this correlation in the case of growing crystals is more difficult due to the impracticality of in situ measurement of the acting thermomechanical stress values. As pointed out above, only the elastic term is responsible for dislocation movement, and thus for the collective dislocation rearrangement in cells. Considering that the subgrain generation is initiated shortly after the onset of plastic deformation [6.125] it can be assumed that the cell formation process takes place immediately behind the growing interface and is completed in the course of plastic relaxation. Thus, the frontal elastic strain acting immediately after the propagating phase boundary can be assumed to be the driving force. This stress value is today readily calculable by global modeling. Therefore, the authors [6.20, 126, 129] used the calculated frontal thermoelastic shear stresses of growth situations, being identical to the real growth positions of each crystal from which the EPD distributions and cell size measurements were taken. The correlation between d and τ^{-1} in the form of (6.28) with $\alpha K = K'$ is shown in Fig. 6.11b. For comparison, the results from deformed metals as well as the slopes for NaCl and LiF are included [6.128, 130]. As can be seen, for cell sizes smaller than $700 \mu\text{m}$ and calculated stresses larger than about 1 MPa, the functional slope is similar to those of deformed materials. Independent of the growth conditions, it was found that d is inversely proportional to τ^{-1} . Obviously, in this region dislocation glide is the prevailing driving force for cell formation, due to the fact that the stress is larger than the critical resolved shear stress. In the case of larger cell dimensions the trend changes, showing a slope smaller than -1 . In these regions a resolved shear stress of $\tau < 1 \text{ MPa}$ was calculated. One can suppose that, for such very low thermomechanical stress, even below the critical resolved shear stress ($\tau_{\text{CRSS}} \approx 0.5 \text{ MPa}$), glide-driven plastic relaxation can no longer be the prevailing driving force for cell formation. Other cell structuring mechanisms must become dominant, such

as point-defect-controlled diffusive creep. This could be in accordance with the observation that the residual dislocations in low-EPD GaAs VGF crystals probably no longer lie within the basal glide system [6.131, 132].

A number of theories have been proposed to account for the stress dependence of the cell size [6.117]. It is usually thought that the decreasing cell dimension with increasing stress is due to cell splitting in the course of growing stress, leading to progressive construction of new walls [6.118]. Newer papers favor a stochastic dynamics of the entire dislocation ensemble [6.117, 125] whereby the dislocation-free regions emerge and vanish in a fluctuating fashion in the course of the acting elastic stress. Until now, however, the question is whether the cell patterning is driven energetically or by a self-organizing process, in the former case by equilibrium, or in the latter by nonequilibrium thermodynamics where the entropy production is stopped, leading to dissipative structuring. There are well-known facts to be stated for energy-related processes. In the classical sense, the driving force for network formation is the reduction in strain energy resulting from the clustering (i. e., mutual field screening) of dislocations in cell boundaries. It is important to note that, for the formation of cells with globular morphology, in addition to dislocation glide, even spatial mechanisms such as climb and cross-glide are absolutely required [6.133]. However, the process of plasticity cannot be explained exclusively by equilibrium thermodynamics due to the presence of typical preconditions for irreversibility, such as temperature and stress gradients during the growth process. Hence, a growing crystal can be treated as a thermodynamically open system with continuous import and export of entropy. As a result, a rate of entropy is produced within the crystal, evoking self-ordered patterning of the stored dislocations. Much more fundamental co-working between crystal growers and theoretical physicists is required to clarify this still open problem.

Grain Boundaries

In numerous melt-grown compound crystals, such as in as-grown CdTe, PbTe, and CaF_2 , for example, the cell arrangement resembles the classical low-angle grain boundary structure. The grain matrix contains mostly isolated dislocations and the walls are formed very abruptly, consisting of only one row of dislocation pits. Sabinina et al. [6.134] investigated the cell wall structure in melt-grown CdTe samples by transmission electron microscopy and observed that the dislocations that constitute the boundaries are nearly all parallel

and most have the same Burgers vector. Such behavior is well known from the standard type of polygonized low-angle grain boundaries containing only the excess dislocations of similar Burgers vector after the annihilation process is completed. Obviously, in such crystals the DD contributes much more effectively to substructure ripening than in Cu and GaAs. Also, the larger disorientation angle between the neighboring cells refers to a typical polygonized grain-boundary structure. Tilt angles of 60–120 arcsec were reported for melt-grown CdTe crystals. Higher disorientation angles in the range of 2–30 arcmin, and in some cases even up to 3°, have been ascertained in PbTe crystals. Such a feature is also characteristic of dielectric materials such as CaF₂ and NaCl [6.135, 136]. It is obvious that in these crystals we have to deal with typical well-ripened grain boundaries, i. e., primary subboundaries, which are often superimposed by cellular structure and secondary subboundaries formed previously [6.136]. The scheme in Fig. 6.12 shows the possible stages of dislocation patterning during crystal growth beginning from cell formation towards a ripened small-angle (primary) grain-boundary structure. Depending on the dislocation mobility (highest in CdTe, PbTe), intrinsic point defect content (lowest in InP), and stacking fault energy (lowest in InP, CdTe), the ripening time and frozen-in contents are, however, different in various materials.

Conventionally, a low-angle grain boundary structure, formed by the above-discussed mechanism of dynamic polygonization, still belongs to a single-crystalline state. It is convenient to separate grain boundaries by the extent of the misorientation between two grains $\Theta[\text{rad}] = b/h$ (where h is the dislocation spacing within the grain boundary). Whereas a low-angle grain boundary is composed of an array of dislocations and its properties and structure (i. e., boundary energy) are a function of the misorientation, large-angle grain boundaries are those with a misorientation greater than 10–15° and are normally found to be independent of the tilt angle. A crystal with such grain structure is considered polycrystalline. It can be appear by:

- i) Spontaneous nucleation in unseeded melt growth processes
- ii) Disturbance of the heat balance between melt and solid phases
- iii) Prenucleation in a supercooled melt region before the growing interface.

Also a cellular interface shape, generated under conditions of morphological instability (Sect. 6.2.3), can

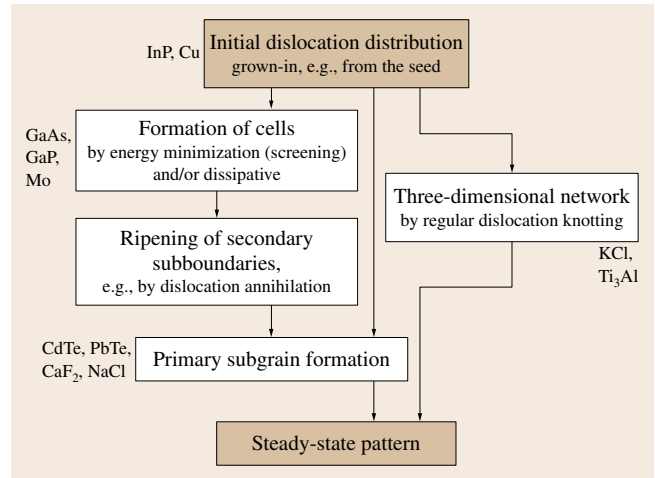

Fig. 6.12 Schematic demonstrating the different types and ripening stages of dislocation substructures that may develop from an initial uniform dislocation distribution. Some materials with typical related patterns, observed after crystallization, are added (after [6.136])

produce large-angle grain boundaries elongated parallel to the growth direction. Large-angle grain structure is a typical feature of cast solar silicon, affecting the photovoltaic efficiency (Table 6.1).

An interesting phenomenon can be observed during the Bridgman growth of semiconductor compounds with high ionicity, e.g., high degree of association in the melt (over 90%), such as CdTe and ZnSe [6.28, 137, 138]. There is a correlation between the number of large-angle grains and superheating of the melt before the crystallization process without an artificial seed is started (Fig. 6.13). Obviously, the high degree of association in slightly overheated melts causes stochastic preformation of structural elements (rings, chains, tetrahedrons), and their docking at the interface markedly affects the single crystallinity. Contrary to that, at a high level of superheating, the melt structure is altered to nearly monomolecular type, promoting nearly grain-free growth.

Dislocation Bunching

Dislocation bundles, often described as gnarls, tangles or clusters, mostly appear sporadically and in isolation. Once nucleated they may propagate through the whole growing crystal, typically parallel to the direction of solidification. Such defects have been detected in GaAs and InP crystals, independently of the growth method. Even in VGF crystals they have been observed. Typi-

Fig. 6.13 The number of grains with large-angle boundaries in VB-grown ZnSe crystals in dependence on the degree of superheating before crystallization. The growth process was started by spontaneous nucleation within the ampoule tip (after [6.138])

cally, they appear in cast silicon ingots too. They are also known from plastically deformed metals and are often called veins. Figure 6.14 shows such bundles as detected on etched wafers of some VCz GaAs crystals. As was revealed by EPD and LST analysis, such bundles consist of very high-density parallel-arranged sessile dislocations. Principally, one has to differ between two types of *bunching*. They can be originated from inclusions (type 1) and contain a characteristic core of the second phase, or they may consist of a high number of tangled dislocations only (type 2) [6.20]. At first glance the two types are often not distinguishable and a locally good resolving analysis is required to differentiate between them.

Today the genesis of type 1 defects is well understood [6.56, 97, 139]. For instance, in GaAs they appear if Ga-rich inclusions are presented. Possible preconditions are growth from Ga-rich melts and/or the use of nonstoichiometric seed crystals already containing

Ga inclusions. They have been also found in VB/VGF-grown CdTe crystals if growth from nonstoichiometric melts was employed [6.140]. In LEC crystals the main origin, however, is an unprotected dissociating crystal surface if it is in contact with too hot a gas ambience. In the case of GaAs the selective As evaporation releases Ga droplets penetrating into the crystal by a traveling solvent mechanism towards increasing temperature, i.e., following the growing interface [6.56, 97]. Usually, behind such defects, a tail of as-generated misfit dislocations are released [6.56, 139]. This mechanism makes LEC growth of semiconductor compounds in low temperature gradients impossible. Its prevention requires the protection of the crystal surface, whether by full encapsulation Czochralski measures (FEC), or VB/VGF or control of the thermodynamic equilibrium with the surrounding gas phase by partial pressure of the volatile component (VCZ mode). Considering these conditions, today type 1 defects are completely preventable.

There are various formation concepts for type 2 dislocation bundles. Mostly they appear at concave parts of the crystallization fronts where favorable conditions of dislocation focusing exist [6.141]. According to etching analysis, dislocation gnarls are mostly localized at the concave-to-convex transition regions on the (110) axis (Fig. 6.14a). Obviously, this has to do with collision of dislocation glides along the basis glide system $\langle 110 \rangle \{111\}$ according to the Schmidt contour. Once they are formed they follow the propagating crystallization front through the whole crystal, as was theoretically derived by Klapper et al. [6.141]. This fact was proved very carefully in GaAs crystals by Shibata et al. [6.142]. Wang et al. [6.143] attributed such bundles to localized composition variation, i.e., stoichiometry fluctuations, along the interface area, which create dislocation sources by vacancy agglomeration. Such instabilities are conceivable if convection-driven turbulence is present in the melt phase. Even newer concepts on stressed metals couple dislocation bunching with oscillating strain [6.144, 145]. The results of simulations demonstrated that, under cyclic loading regions of low and high dislocation density, a vein structure is formed. From that arises the question: do convective oscillations or even heating temperature fluctuations during a melt growth process play a similar stimulating role in dislocation bunching? Further investigations are required to solve this phenomenon. Generally, it is proved experimentally that the probability of bunching decreases with flattening of the growing interface. In fact, a slightly convex morphol-

Fig. 6.14a–c Dislocation bunching in melt-grown crystals. **(a)** Dislocation bundles in a GaAs wafer positioned along $\langle 110 \rangle$ directions. The comparison with longitudinal striation analysis shows that the bundles are generated at the concave parts of a markedly w-shaped interface (after [6.20]) (reproduced by permission of Elsevier). **(b)** Magnified dislocation bundles in GaAs. **(c)** Dislocation bundles in cast silicon used for solar-cell production passing through the whole ingot as veins (see also Fig. 6.7b; **(c)** courtesy of U. Juda from IKZ Berlin)

ogy, if the ratio between the diameter of the interface curvature r_{IF} and the crystal radius r is > 0.5 , proves to be optimum for prevention of dislocation bunching [6.20].

A special case of slip line assembling has been found in *lineages* formed like wavy *dislocation walls*. According to [6.120] in GaAs such lineages are composed of an enormous number of slip lines piled up within thin stripes parallel to $\{110\}$. Due to their slope against the crystal edge when the interface was slightly convex they could be related to isotherm curvature. After Ono [6.146], lineages are the result of slip interactions leading to sessile dislocations by the Lomer–Cottrell mechanism. The degree of waving is influenced by high-temperature climb processes. Probably, they reflect a morphological feature of the growing interface and are, therefore, coupled with the melt–solid phase boundary. Today the exact origin of lineages is still unclear. From growth experiments it follows that they can be prevented by nearly flat interface shapes when only minimal thermoelastic stresses are present.

6.3.3 Dislocation Engineering

Dislocation engineering deals with practical measures of control of dislocation density and patterns or even their prevention in situ, i.e., during the crystal growth process. Generally, for dislocation-reduced growth of

compound and mixed crystals with large diameters, the proper combination of the following conditions are required:

- i) Use of a *dislocation-free seed* crystal, in order to prevent grown-in dislocations being the most serious sources of dislocation multiplication
- ii) Achievement of a strongly *uniaxial heat flow* with very small temperature gradients, i.e., nearly flat isotherms at all stages of the growth process
- iii) *Omission of fluid encapsulants* (boric oxide), the presence of which introduces marked thermomechanical stresses at the crystal periphery, and maybe its replacement by a *detached growth mode* [6.147]
- iv) In situ *stoichiometry control* by partial vapor pressure regulation over the melt in order to reduce the intrinsic point defect content which promotes high-temperature dislocation multiplication by climb and also cell structure formation
- v) Prevention of *constitutional supercooling* at the interface by proper selection of a noncritical G/R ratio
- vi) Minimization of atmospheric *pressure fluctuations* around the growing crystal to prevent heterogeneous dislocation rearrangements in bundles and veins.

The highest-temperature nonlinearities, and hence related thermal stress values, increasing very sensitively with diameter, appear in LEC crystals. Today, in such undoped 4 and 6 inch GaAs crystals, the

mean dislocation densities are $(5-7) \times 10^4$ and $(1-2) \times 10^5 \text{ cm}^{-2}$, respectively. The situation can be improved by using modified Czochralski growth with low thermal gradients, for which the vapor-pressure-controlled Czochralski (VCZ) method is available [6.56]. In 6 inch SI (semi-insulating) VCz crystals of more than 20 cm length (25 kg) the average etch pit density (EPD) along the $\langle 110 \rangle$ and $\langle 100 \rangle$ directions can be reduced to $(1.8-2.6) \times 10^4$ and $(2-3) \times 10^4 \text{ cm}^{-2}$, respectively. Minimum values of $(6-8) \times 10^3 \text{ cm}^{-2}$ were ascertained near the $r/2$ region (where r is the wafer radius). In 4 inch VCz crystals a somewhat lower average EPD of $(5-10) \times 10^3 \text{ cm}^{-2}$ was found [6.148].

The best EPD results, however, can be obtained by the VGF method, matured on the industrial scale since the mid-1990s as the most promising growth variant for important semiconductor (InP, GaAs, CdTe), fluoride (CaF_2), and oxide ($\text{Bi}_4\text{Ge}_3\text{O}_{12}$ (BGO), $\text{Pb}(\text{Mg}, \text{Nb})_{1-x}\text{Ti}_x\text{O}_3$ (PMNT), $\text{Pb}(\text{Zn}, \text{Nb})_{1-x}\text{Ti}_x\text{O}_3$ (PZNT)) compound crystals. The decisive technological measure proved to be the maintenance of a uniaxial heat flow through the growing crystal during the whole growth run by proper control of the cooling rate between a top and bottom heater flanked by a booster heater to avoid radial heat outflow [6.149]. In undoped GaAs VGF crystals with diameters between 3 and 6 inch, dislocation densities in the range from 500 to 5000 cm^{-2} have been reported [6.150, 151]. Müller and Birkmann [6.152] succeeded in the growth of Si-doped 4 inch GaAs crystals with the lowest EPD of 31 cm^{-2} by optimized VGF. The few residual dislocations in $\langle 100 \rangle$ -oriented crystals are accumulated cross-like along the $\langle 100 \rangle$ directions, obviously connected with the pronounced joint of the $\{111\}$ facets along the $\langle 100 \rangle$ directions in the crystal cone after the seed. This phenomenon favors growth with a flat bottom from a seed of the same diameter [6.153, 154] in order to maintain the rotational symmetry without pronounced faceting.

Another phenomenon to be controlled in situ is dislocation cell patterning. This problem has not yet been solved on an industrial scale. However, there are already some in-principal laboratory experiences usable for future melt growth improvements. First, independently of the materials used, the cell forma-

tion can be reduced very effectively by doping. No cell structuring was observed in GaAs doped with In or Si at concentrations $> 10^{18} \text{ cm}^{-3}$. Such an effect is due to the impurity gettering at the dislocation core increasing with temperature because of the increasing diffusion rate. As a consequence, the yield stress is enhanced by dislocation locking. No low-angle grain structure was found in CdTe and PbTe crystals when solution hardening by mixing components Se ($x > 0.4$) and Sn ($x > 0.15$) was provided, respectively. However, there is the drawback of segregation when dopants are added to the melt (Sect. 6.2.2) and the danger of morphological interface instability by constitutional supercooling (Sect. 6.2.3). Obviously, the best way to exclude dislocation patterning is reduction of the dislocation density by minimization of the thermomechanical stress. In undoped GaAs it was observed that at ρ values $< 5 \times 10^{-3} \text{ cm}^{-2}$ the cell structure began to disappear. However, for compound crystals with larger diameters over 100 mm the attainment of such low dislocation densities is not yet solved empirically when hardening dopants are not added. Hence, current efforts are directed to homogenization of the thermal field in the growing crystals in order to reduce the dislocation multiplication and mobility by minimizing the thermomechanical stress. Another important way to prevent cell patterning is the minimization of the native point defect content by in situ control of stoichiometry during growth. The stoichiometry can be regulated by the partial pressure of the volatile component over the melt, applying an extra heat source within the growth chamber [6.56]. Using such a VCz arrangement without boric oxide encapsulant, the cellular structure could be suppressed in undoped GaAs crystals when the stoichiometry was controlled by growth from Ga-rich melt composition [6.155, 156]. Recently, this result was confirmed theoretically [6.157]. The stored dislocation density can be reduced under stoichiometric growth conditions. This was achieved for GaAs by horizontal Bridgman growth [6.158], hot-wall Czochralski method [6.159], and VCz [6.155]. Tomizawa et al. explained it as a result of the lowest intrinsic point defect concentration taking part in dislocation motion and multiplication.

6.4 Second-Phase Particles

The presence of second-phase particles, often named COPs (crystal-originated particles), markedly affects the optical and electronic bulk quality as well as the

surface perfection of epitaxial substrates (Sect. 6.1.2). COPs are some of the most studied harmful objects in as-grown crystals. They are present even in un-

doped $A^{II}B^{VI}$ (e.g., CdTe [6.28, 140], ZnSe [6.137]), $A^{III}B^V$ (e.g., GaAs [6.160, 161]), and $A^{IV}B^{VI}$ (e.g., PbTe [6.162]) compounds, but also in numerous oxides (e.g., $Gd_3Ga_5O_{12}$ (GGG) [6.163]) and fluorides (e.g., CaF_2 [6.164]). One of the most serious consequences of compound crystal growth under conditions of native point defect formation is their condensation in precipitates and microvoids. This phenomenon is due to the retrograde behavior of the boundary of the compound existence region, and therefore related to nonstoichiometry (Sect. 6.2.1). In addition, foreign particles, melt–solution droplets of the excess component, and gas bubbles can be incorporated at the growing melt–solid interface.

As explained in detail by Rudolph et al. [6.28, 165], it is important to distinguish between these two different second-phase particle formation mechanisms:

- i) Precipitation
- ii) Inclusion incorporation.

A schematic sketch of the origins of both processes is shown in Fig. 6.15, where their relations to the phase diagram are also illustrated.

In the case of a particle with near-spherical geometry it is known that the total concentration of the second-phase component N_i (in cm^{-3}) can be estimated

according to the formula [6.28]

$$N_i = \frac{4\pi\rho_i N_A}{3A_i} \sum_{i=1}^n r_i^3 \rho_i, \quad (6.29)$$

where ρ_i and A_i are the density and the relative atomic mass of the second-phase component, respectively, N_A is Avogadro's constant, r_i is the particle radius, and i is an index for each class of particle diameter.

6.4.1 Precipitates

Fundamentals of Generation

Precipitates are formed due to the retrograde solubility of native point defects in nonstoichiometric solid compositions (Fig. 6.15). As the as-grown crystal is cooling down, the solidus is crossed and nucleation of the second phase takes place. Probably, Ostwald ripening has to be considered. Favored sites of precipitate ripening are dislocations, as has been concluded from IR laser scattering tomography (e.g., [6.120, 161]; Fig. 6.16). Average precipitate densities of about 10^8 and up to 10^{12} cm^{-3} have been found in GaAs [6.160] and CdTe [6.28], respectively. Typical sizes between 10–100 nm have been determined for As precipitates in GaAs [6.166] and Te precipitates in CdTe [6.167]. Half-empty precipitates have been found by transmission electron microscopy (TEM) in GaAs [6.168] and

Fig. 6.15 Nonstoichiometry-related effects of second-phase particle formation in a growing compound crystal explained by a sketched phase diagram with elongated phase extent. The segregation evokes the rejection, and hence enrichment, of excess component at the interface that may lead to inclusion incorporation. Homogeneous (matrix) and heterogeneous (decoration) precipitations take place due to second-phase nucleation at the retrograde slope of the solidus curves, probably with subsequent Ostwald ripening

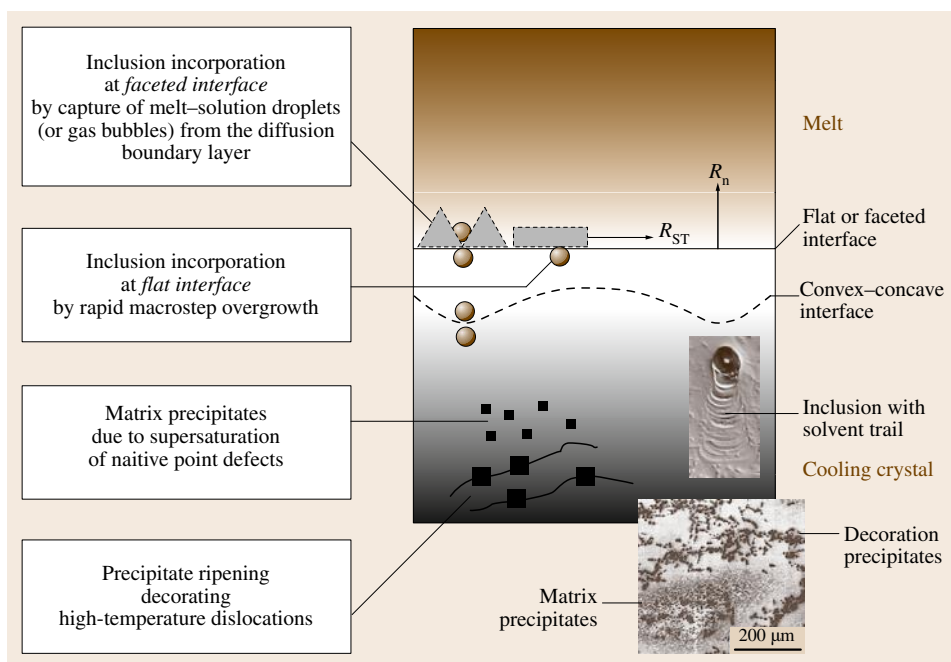

Fig. 6.16 Scheme of different inclusion incorporation and precipitation mechanisms during crystal growth from melt. Two images showing a Ga inclusion with traveling Ga-rich solvent trail and As precipitates in GaAs crystals (after [6.57, 161], reproduced by permission of Elsevier)

CdTe [6.169], probably caused by vacancy condensation in one of the sublattice components accompanied by conglomeration of excess atoms of the opposite sublattice.

In CdTe both tellurium and cadmium precipitates have been found [6.170]. This depends on the melt composition from which the crystal was grown (Te- or Cd-rich, respectively). According to the CdTe phase diagram their density can be effectively minimized by growth under near-stoichiometric conditions [6.28]. Contrary to this, in melt-grown GaAs crystals, only As precipitates were observed. Fornari et al. [6.166] found a correlation between As precipitate size and deviation from stoichiometry. Whereas at the stoichiometric melt composition ($x_L = 0.5$) the diameter is about 120 nm, from Ga-rich melts As precipitates of 40 nm diameter form, even when the mole fraction is markedly Ga-enriched ($x_L = 0.425$). This would be in accordance with a GaAs existence region located completely on the As-rich side, as obtained from current thermochemical calculations and stoichiometry-controlled VCz experiments [6.19, 47, 48].

Control of Precipitate Density

There are two effective ways to minimize the precipitation concentration:

- i) In situ control of stoichiometric crystal composition (see also Sect. 6.2.1)
- ii) Postgrowth annealing under controlled partial pressure.

As was demonstrated by Kießling et al. [6.57] in VCz growth of GaAs without boric oxide encapsulant, melt compositions less than or around a mole fraction of $x_L \approx 0.45$ yield near-stoichiometric crystals essentially without precipitation.

Oda et al. [6.53] developed a multiple postgrowth wafer annealing technology for semi-insulating GaAs. Highly uniform substrates with markedly decreased arsenic precipitate density were obtained. Postgrowth wafer annealing was also successfully used by other authors for InP, GaP, CdTe, and ZnSe wafers.

6.4.2 Inclusions

Incorporation Mechanisms

In contrast to precipitates, inclusions are formed by capture of melt-solution droplets, gas bubbles or foreign particles from the diffusion boundary layer adjacent to the growing interface and enriched by the rejected excess component (Fig. 6.15). Preferred sites are reentrant angles of grain boundaries and twins crossing the interface. Dinger and Fowler [6.171] found lineages

made of tellurium along the growth direction of CdTe crystals grown from Te-rich melt. They attributed this phenomenon to the enhanced cellular growth caused by constitutional supercooling. The inclusions are concentrated in the interlamella notches (Fig. 6.16). Typical inclusion diameters are 1–2 μm , but sizes up to 30 μm have been also observed in HB and VB CdTe crystals grown without Cd pressure control [6.28]. Their axial distribution increases slightly with increasing excess component by segregation. Melt–solution inclusions due to nonstoichiometric melt compositions show a specific crystallization genesis within the already solidified matrix [6.140]. Often they are embedded in a negative polyhedron formed by adjacent zincblende {111} planes. An inclusion could also be captured at a nearly flat interface by an overgrowth or embedding mechanism, as discussed by Chernov [6.38].

Prevention of Inclusion Trapping

There are two essential technological measures against inclusion incorporation:

- i) Growth from the congruent melting point (mostly located close to stoichiometry)
- ii) The choice of undercritical growth velocities.

Furthermore, accelerated crucible rotation techniques [6.85] and control by ultrasonic [6.86] or nonsteady magnetic fields [6.92–94] can be adopted as effective additional steps to disassemble phase boundary layers in melt-growth processes.

6.5 Faceting

When Hulme and Mullin [6.174] looked in the 1950s at the segregation of a number of solutes in InSb they found that the segregation coefficient was different for crystals grown in a $\langle 111 \rangle$ direction as compared with growth in any other direction. Using radiotracer

Fig. 6.17a,b Dopant redistribution in crystals grown with core facets. **(a)** Autoradiographs of a longitudinal section of $\langle 111 \rangle$ -oriented InSb crystals doped with Te. The *bright central column* in each section is a region of enhanced Te concentration where the crystals grew with a faceted interface (after [6.2,3]). **(b)** Optical diffraction along a longitudinal cut of an InP crystal doped with sulfur. The core region corresponding with {111} facet shows enhanced S concentration (after [6.173], reproduced by permission of Elsevier) ►

Note, even microgravity conditions are not favorable for the prevention of inclusion incorporation. Salk et al. [6.172] demonstrated during growth under microgravity that the danger of Te inclusion incorporation in CdTe is markedly increased. Due to the absence of convection in the melt the enrichment of the excess component at the interface, and hence the thickness of the diffusion boundary layer, is increased. This enhances the probability of inclusion capture. The growth of inclusion-reduced crystals in space proved to be successful only when well-controlled melt mixing by a rotating magnetic field was applied [6.172].

Chernov [6.38] estimated a critical interface rate R_{cr} to prevent inclusion or gas bubble incorporation that depends on the particle (bubble) radius r_{in} , the interface energy α , and the dynamical viscosity of the melt η as

$$R_{\text{cr}} \leq \left(\frac{0.11B}{\eta r_{\text{in}}} \right) \left(\frac{\alpha}{B r_{\text{in}}} \right)^{1/3}, \quad (6.30)$$

where B is a constant ($\approx 10^{-17} \text{ cm}^2 \text{ kg s}^{-2}$). For instance, in the growth of GaAs crystals from the melt with $\eta = 2.8 \times 10^{-5} \text{ kg cm}^{-1} \text{ s}^{-1}$ a solid spherical foreign particle with $r_{\text{in}} = 1.5 \times 10^{-3} \text{ cm}$ and $\alpha = 0.19 \text{ kg s}^{-2}$ would be rejected from the propagating interface if its normal rate R_{n} is $< 2 \text{ mm/h}$. Chernov showed that the hydrostatic pressing force of gaseous bubbles towards the interface plane is lower than that for solid particles. Hence, prevention of incorporation of microbubbles (e.g., of gaseous arsenic) of the same radius requires consideration of a somewhat enhanced critical velocity of about 8 mm/h.

techniques, they demonstrated that a nonequilibrium concentration was incorporated into those parts of the crystal that had been grown on a faceted interface [6.2, 3] (Fig. 6.17a).

Until today faceting plays a problematic role during crystal growth, especially of oxide materials [6.175, 176]. Facets are the macroscopic indication of a given crystallographic structure and express, therefore, the natural tendency of single crystals to form polyhedra. Hence, the higher the crystal quality, the more developed the facets. This means that they are not defects in reality, but rather a serious cause of dopant and solvent redistributions as well as thermal field inhomogeneities due to their enhanced radiation effects. Further, facets at the rim of a pulling crystal may affect meniscus stability. Careful observation of a growing LiNbO₃ crystal periphery has revealed sudden repelling of the melt from a facet followed by rewetting, i.e., the meniscus jumps several mm down and then up. Such meniscus instability can lead to spontaneous nucleation and subsequent growth of polycrystals [6.176].

Facets form on crystal planes, for which 2-D nucleation is required in order to initiate the growth of a new layer. On nonfaceted (atomically rough) surface atoms can be added singly without the need for nucleation. At a given growth temperature, all crystals will have some surfaces which are rough. However most crystals will have one or more surfaces that are atomically smooth requiring nucleation, especially dielectric materials. Jackson [6.37] proposed a simple relation (Jackson factor α) for the faceting probability

$$\alpha = \frac{\Delta H_{SL}}{k_B T_m} \frac{w}{u} \quad (6.31)$$

(T_m is the melting temperature; w is the number of nearest neighbors of an atom in the growing face; u is the

number of nearest neighbors of an atom in the crystal), which indicates that the magnitude of the entropy of fusion ΔH_{SL} of a material is the guide to its likelihood of forming facets during growth, i.e., materials having a low entropy of fusion (such as metals with $\alpha < 2$) have the lowest probability. In contrast, dielectric crystals with large ΔH_{SL} due to their strong ionic bond energy show a high α factor (> 2), and hence the greatest faceting probability. The common semiconductor materials, with their covalent bonding and $\alpha \approx 2$, tend to form facets during melt growth only on their most closely packed {111} planes, i.e., where the w/u ratio is nearest to unity, or in other words the surface energy is lowest. For instance, in silicon for the {100} and {111} planes the Jackson factors for $\alpha_{\{100\}}$ and $\alpha_{\{111\}}$ are 1.75 (atomically rough) and 2.63 (atomically smooth), respectively.

A further geometric requirement for facet formation during crystal growth from melts is that the radial temperature gradient be such that the freezing-point isotherm is convex when viewed from the crystal (Fig. 6.18a). This ensures that, if the crystal starts to lag behind the isotherm, it experiences increased supercooling at the facet, which ultimately promotes the nucleation of a new layer (note that, the higher the crystal perfection, i.e., the lower the dislocation density, the larger the supercooling). The lateral extension of the facet d is proportional to the supercooling ΔT [6.176] (Fig. 6.18a) as

$$d = 2\sqrt{\frac{2r_{IF}\Delta T}{G_r}}, \quad (6.32)$$

where G_r is the radial temperature gradient, ΔT is the undercooling, and r_{IF} is the radius of curvature of the interface. As can be seen, d increases with decreasing convexity of the interface, i.e., reducing radial temperature gradient. The rapid lateral growth tends to trap in the surface-adsorbed (equilibrium) solute concentration, thereby increasing the effective interface segregation coefficient of solutes that are preferentially adsorbed at the interface. The most dramatic effect occurs with Te-doping of InSb. Here the equilibrium segregation coefficient of Te is ≈ 0.5 , whereas the effective segregation coefficient on the {111} facets is ≈ 4.0 , giving the remarkable ratio 8 : 1 [6.177].

For several years the symptom of faceting at growing interfaces has been considered in numeric modeling of crystal growth processes [6.178]. To do this, the transport phenomena must be coupled with interfa-

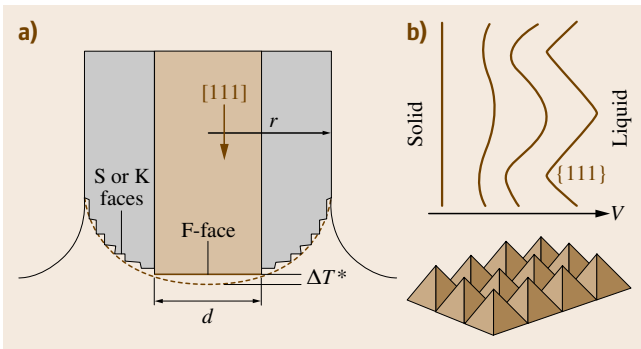

Fig. 6.18a,b Faceting phenomena at the growing melt–solid interface. **(a)** Sketch of Czochralski growth of a crystal with diamond or zincblende structure in $\langle 111 \rangle$ direction with convex interface where a $[111]$ facet is formed. **(b)** Morphological instability of a growing interface where microfacets are formed (after Hurle and Rudolph [6.2, 3])

cial attachment kinetics. Hence, the isotherm condition, typically employed at the melt–crystal interface, is replaced by an equation accounting for undercooling due to interface kinetics. As a result, the interplay between evolving thermal fields and anisotropic interface kinetics is investigated. In particular, the evolution of facets

6.6 Twinning

Grown-in twins are one of the most serious macroscopic defects, the presence of which makes a crystal of no commercial use because of the twin-induced growth disorientation over the whole crystal body (Fig. 6.19). To date, there is no absolutely reliable measure to prevent twinning due to the stochastic character of its appearance. However, one can rank the material and growth parameters most responsible for enhancing the twinning probability. *Gotschalk et al.* [6.181] correlated it with the stacking fault energy, whereupon the greatest danger of twinning exists in materials with high ionicity, showing the lowest stacking fault energies. In fact, InP and CdTe with degrees of ionicity of 42% and 72%, i. e., stacking fault energies of 18 and $11 \times 10^{-7} \text{ J/cm}^2$, respectively, show an extremely high twinning statistics among the semiconductor compounds. Growth conditions enhancing twin appearance are:

- i) Temperature instabilities, i. e., remelting of the interface
- ii) Presence of impurities
- iii) Foreign particles swimming on the melt surface
- iv) Interface contact with wetting inner container walls
- v) Morphological instability of the crystallization front

The recently successful twin-free growth of GaAs crystals from Ga-rich melts without boric oxide encapsulant by the VCz technique [6.156] refutes the former conclusion that twin-free growth was highly improbable for growth at marked deviation from stoichiometry, even of GaAs from Ga-rich melts [6.182].

In the diamond and zincblende structures, twinning is closely related to facet formation (Sect. 6.5) and specified by a rotation of the lattice by 60° about a $\langle 111 \rangle$ axis, the twin lying on the orthogonal $\{111\}$ plane. As a result, a former $[001]$ -oriented crystal after twinning becomes completely disoriented with the $[221]$ axis (Fig. 6.19a). It was recognized early on by *Billig* [6.183] that such twinning occurred principally on $\{111\}$ facets, which form adjacent to the three-phase boundary of melt, crystal, and ambient. *Billig* studied Ge crystals

and the dependence of their size on growth conditions, especially of oxide crystals such as $\text{Y}_3\text{Al}_5\text{O}_{12}$ (YAG), are explored. Of course, most realistic modeling of crystal growth systems involving partial faceting will usually require three-dimensional analysis techniques [6.179].

where the problem is not serious and totally avoidable with carefully controlled growth. The problem is more serious in the III–V compounds, notably In-containing ones such as InSb, InAs, and InP.

The mechanism by which such twins form during growth defied explanation for many years, but in 1995, *Hurle* [6.182] provided a possible thermodynamic description based on ideas due to *Voronkov* [6.184], which can explain the key features of the process. The model demonstrates that, because of the orientation dependence of interfacial energies in the presence of facets, there is a configuration of the three-phase boundary for which, for sufficiently large supercooling, the free

Fig. 6.19a–c Formation of grown-in twins in Czochozralski crystals with diamond and zincblende structures. **(a)** Sketch showing different kinds of twins and the misorientation of the whole crystal from the initial $[001]$ into $[122]$ direction after generation of a single twin. **(b)** Twinning on $\{111\}$ facets (white arrows) at the shoulder region of a InP crystal revealed by *Inada* [6.180] (reproduced by permission of Elsevier). **(c)** Scheme demonstrating the stacking fault (i. e., twinned) 2-D growth mode along the $\{111\}$ facets when a misoriented nucleus is generated at the vapor–liquid–solid (VLS) interface

energy of formation of a critical nucleus is actually lowered by forming that nucleus at the three-phase boundary in twinned orientation. This will occur only if a critical angle of conical growth presenting a portion of crystal surface normal to $\langle 111 \rangle$ is sampled during the growth.

Such a twinned nucleus is thermodynamically favored if the supercooling exceeds the critical value

$$\delta T^* = \left(\frac{\sigma T_m}{h \Delta H_{SL}} \right) A^*, \quad (6.33)$$

where σ is the twin plane energy, T_m is the melting temperature, h is the nucleus height, ΔH_{SL} is the latent heat of fusion, and A^* is the reduced work of formation of a nucleus intersecting the three-phase boundary. Experimental test of this model on InP had been provided by the groups of Müller [6.185] and Dudley [6.186, 187]. Especially Dudley et al. [6.187] found, by synchrotron x-ray anomalous scattering analysis of as-grown InP crystals, that not 60° twinning but 180° rotation between the matrix and the twins takes place. They observed that twinning immediately follows the formation of a $(1\bar{1}\bar{5})$ external shoulder facet which, upon twinning was converted to a $(\bar{1}11)$ one. This can only occur when the edge facets exist in a region where the shoulder angle is close to 74.21° . The result demonstrates the importance of shoulder geometry during growth. Additionally, it was ascertained that twin nucleation occurs preferentially on $\{111\}_P$ faces due to the 30% lower surface energy than those of $\{111\}_{In}$. In GaAs preferential twinning on $\{111\}_{As}$ planes has been reported, showing a 12% lower surface energy than that of the Ga-terminated one.

6.7 Summary

The most important defect types and possible origins during crystal growth from the melt have been discussed. Today, most of the defect-forming mechanisms are well understood. However, some important questions still remain to be solved. For instance, the influence of the degree of association of the melt on the growth kinetics, which probably plays an essential role in II–VI systems, requires further consideration. Further, the dislocation patterning and bunching mechanisms in correlation with the growth conditions are not yet completely decoded. Also, the main origin of twinning has not yet been revealed.

Many LEC and Bridgman experiments have demonstrated that the twin probability is markedly reduced if the temperature oscillations of the growth system, and therefore excursions of the angle of the contacting meniscus, are minimized. This is due to the reduced probability of encountering the critical angle described above when the meniscus angle fluctuations are reduced. In fact, Hosokawa et al. [6.188] succeeded in growing twin-free InP crystal with diameters up to 100 mm by careful maintenance of thermal stability during growth, which was achieved by VCz and applying damping magnetic fields around the melt.

An interesting correlation has been observed by Rudolph during the vertical Bridgman growth of CdTe [6.28] and ZnSe crystals [6.137] by self-seeding. The number of twins was reduced and even prevented when the melt was markedly overheated and held for a longer time before the nucleation process in the ampoule tip was started. Similar results were described by Khattak and Schmid [6.189], with reduced twin formation in CdTe by overheating of the melt to above 110 K. Such a phenomenon can be explained when the well-known high degree of melt association of these materials at low superheating is taken into account. Probably, at a few Kelvin above the melting point, there are still enough preserved melt associates, such as tetrahedra, which can be incorporated into the crystalline phase by a false stacking sequence (e.g., 60° rotated in relation to a correct stacked $\{111\}$ -plane). Witt [6.190] proposed a clustering model of the melt, whereupon the smallest cluster of relative stability capable of nucleating oblique twins comprises eight atoms. In general, more investigations of the melt structure and its influence on the growth kinetics are necessary.

Eminent success has been achieved in technological developments. During the last decade, computer-controlled vertical gradient freezing has matured to become the leading industrial production method for semiconductor compound crystals. However, that is not to say that all defects can be avoided. For example, the relatively poor thermal conductivity and low yield stresses of III–V and II–VI compounds as compared with Ge and Si mean that it is not possible to reduce the thermal stresses to a sufficiently low level to avoid dislocations.

Scaling up to achieve cost reduction is an ever-present pressure. Increasing crystal diameter increases

the thermal stresses experienced during cooling. Avoiding increased dislocation density requires continual refinement of furnace design, and here computer modeling plays a key role. An additional problem posed by scaling-up is the increased turbulence which occurs in the melt. The use of magnetic fields is being ex-

ploited to achieve damping of this turbulence. Recently, in the author's laboratory, the concept of simultaneous generation of heat and a traveling magnetic field by a heater placed within the growth chamber was successfully tested and its first industrial application started [6.191].

7. Indium Phosphide: Crystal Growth and Defect Control by Applying Steady Magnetic Fields

David F. Bliss

The application of steady magnetic fields during crystal growth of indium phosphide is described, and the effect of the magnetic fields on crystal properties is analyzed. The use of magnetic fields is one of many engineering controls that can improve homogeneity and crystal quality. This method is especially relevant to InP because of the high pressure requirement for crystal growth. Under high pressure, fluid flows in the melt and in the gas environment can become uncontrolled and turbulent, with negative effects on crystal quality and reproducibility. If properly configured, a steady magnetic field can reduce random oscillatory motion in the melt and reduce the likelihood of defect formation during growth. This chapter presents the history and development of magnetic-field-assisted growth of InP and an analysis of the effects of applied fields on crystal quality.

7.1 Historical Overview

The development of bulk InP crystal growth has been historically driven by the commercial telecommunications market for solid-state lasers. InP was chosen because it has a lattice match with the semiconductor compounds that serve as laser materials for fiber-optic communications. Small 2 in diameter wafers were sufficient from the outset to fabricate large volumes of discrete lasers with commercially viable yields. Because of the small size of the lasers, the demand for larger-diameter wafers was slow to gain momentum. Later, during the 1990s, new applications for optoelec-

tronic devices requiring larger-area InP substrates led to the development of 4 in diameter InP crystals. As recently as 2006, a new application for high-speed laser modulation was developed using 6 in InP wafers bonded to silicon [7.1].

Crystal growth of large-diameter InP boules places extreme control demands on the crystal growth environment, which becomes increasingly chaotic as the size of the melt increases. At the melting temperature of 1060 °C, the equilibrium vapor pressure of phosphorus over InP is 27 atm. Controlled crystal growth must

be performed in a pressure vessel exceeding 30 atm. Two principal issues arising from this pressure dependence are the synthesis of a stoichiometric InP compound and the containment of a highly volatile melt. Experiments on compound semiconductor crystal growth from volatile compounds in the 1960s focused on two possibilities: either the crystal must be grown in a completely sealed hot-wall ampoule (Bridgman or gradient freeze method), or the crystal can be pulled using an encapsulant under pressure. Using a pressure-balancing technique, a breakthrough came in 1962 when Metz and a group at Westinghouse [7.2] developed the liquid-encapsulated Czochralski (LEC) method for growth of PbSe and PbTe. The LEC method was later adapted for growth of InP using B_2O_3 as an encapsulant [7.3–5].

The state of the art today for bulk InP crystal growth is still divided between two competing technologies: top-seeded crystal pulling with liquid encapsulation and

vertical growth in a container with bottom seeding. Various names for these techniques have arisen from each unique laboratory research effort. In general, the pulling method has been the most cost-effective, but with high thermal gradients and a high level of strain during growth, the crystals may have high dislocation densities. On the other hand, vertical container growth offers a very low dislocation density because of its low-stress environment, but it is plagued by yield problems due to twinning and interface breakdown in heavily doped crystals. Two recent reviews [7.6, 7] have compared the growth, characteristics, and applications of InP crystals grown by both techniques. This chapter focuses on the development of techniques to control the turbulent melt environment using applied magnetic fields, and characterization to determine the electrical and optical properties of InP crystals after growth and thermal treatment.

7.2 Magnetic Liquid-Encapsulated Growth

Growth of InP in an axial magnetic field has two main advantages: melt stability contributes to reduced incidence of twinning and improved dopant uniformity. On the other hand, the radial temperature gradient is increased by an axial magnetic field because convective heat transfer in the melt is reduced. The resulting convex interface contributes to large hoop stresses during crystal growth, contributing to dislocation multiplication and propagation. On the other hand, if a cusped magnetic field is employed (with two opposing vertical magnetic fields), the radial thermal gradients are predicted to be flatter, since the nonuniform field will not affect radial fluid flow near the surface. Flattening the melt isotherm should reduce the dislocation density of InP crystals. In this chapter we will compare the cusped with the axial magnetic field for InP bulk crystal growth, and evaluate the practicality of imposing a strong axial magnetic field on the melt during growth. To determine if there are advantages in terms of process control, we compare crystallographic defects such as twins, dislocations, and striations under either controlled or uncontrolled environments during crystal growth. A major goal is to determine the effect on melt convection of magnetic field configuration, either axial or cusped.

7.2.1 Evolution of Crystal Growth Under Applied Magnetic Fields

In the 1960s several authors [7.8, 9] pointed out that the application of an external magnetic field would be useful to damp the time-dependent turbulent convective flows in melts during the growth of semiconductors. Experimental support for this concept did not appear in research laboratories until the 1980s [7.10, 11], and more recently it has attracted commercial interest for growth of InP crystals. There are two main advantages which result from magnetic field growth:

1. Thermal fluctuations are reduced, thereby stabilizing the microscopic growth rate, and consequently
2. The diffusion boundary layer is increased, enhancing the uniformity of dopant distribution.

Natural convection and forced convection are two coexisting forces during crystal pulling from the melt, and the magnitude and direction of fluid flow plays a crucial role in heat and mass transfer during growth. In Czochralski growth, both the thermal field and the solute distribution are dominated by convection. However, since most semiconductor melts are metallic in nature, changes to the flow dynamics can be made by applying

a magnetic field. With the application of a static magnetic field, convective forces in the liquid are restricted when the flow crosses the magnetic lines of flux by the Lorentz force \mathbf{L}

$$\mathbf{L} = \mathbf{j} \times \mathbf{B}, \quad (7.1)$$

where \mathbf{j} is the ionic current density vector and \mathbf{B} is the applied magnetic field. The characteristic ratio between the electromagnetic (EM) body force and the viscous force is Ha^2 , where the Hartmann number is

$$\text{Ha} = BR \left(\frac{\sigma}{\mu} \right)^{1/2}, \quad (7.2)$$

where B is the magnetic flux density of the magnetic field, R is the characteristic dimension of the melt, σ is the electrical conductivity of the melt, and μ is the dynamic viscosity of the melt. As the Hartmann number increases, the characteristic velocity of the melt is reduced. Although it is not practical to produce a magnetic flux density sufficiently large to eliminate all melt motion due to natural and forced convection, a strategy of controlling melt motion for dopant uniformity can be achieved with moderate magnetic fields. The model of Burton et al. [7.12] reveals the effect of melt convection on crystal growth. A diffusion boundary layer δ is assumed, beyond which the melt composition is maintained uniform by convection and inside of which transport is by diffusion only. The boundary layer is thus confined by the characteristic melt velocity. After steady state is reached, for an infinite liquid, one can define an effective distribution coefficient k_{eff}

$$\frac{C_S}{C_L} \equiv k_{\text{eff}} = \frac{k_0}{k_0 + (1 - k_0)e^{R\delta/D}}, \quad (7.3)$$

where R is the growth rate and D is the diffusion coefficient for the solute in the melt. This is a useful expression because it relates the composition of the growing crystal to convection conditions and the growth rate. It describes the dopant distribution provided that the thickness of the boundary layer is small compared with the extent of the crucible. For example, an increase in the growth rate or the boundary-layer thickness tends to enhance the effective distribution coefficient towards unity. In the case of an applied magnetic field, the diffusion boundary-layer thickness increases, and hence k_{eff} is closer to 1, resulting in a more uniform incorporation of the dopant. The dopant distribution in magnetic field growth has been modeled by several authors [7.13, 14]. Experimental confirmation of this model will be discussed in Sect. 7.3.2.

7.2.2 Crystal Shaping Measures

The prevailing crystal pulling method is liquid-encapsulated Czochralski growth, named after *Czochralski* [7.15], a Polish scientist who developed a pulling method for growth of metallic rods. Although his work was focused on thin metal rods, Czochralski's name has become associated with the characteristic shape of large single crystals pulled from the melt. Magnetic liquid-encapsulated Czochralski (MLEC) growth is a variant of Czochralski growth with improved control over melt turbulence by application of a static magnetic field. Crystal pulling is initiated immediately after seeding, and as the melt temperature is reduced, a sloped shoulder emerges from the melt with a grow-out angle between 60 and 80°. The phenomenon of growth twinning is a problem in the shoulder region because the shoulder angle may traverse a critical angle where twinning is likely to occur. As will be shown in Sect. 7.3.2, to avoid the problem of growth twinning, the shape of the crystal must be controlled reproducibly. In Fig. 7.1 we see an example of an InP MLEC crystal grown with a controlled shape to avoid the critical angle

Fig. 7.1 MLEC InP Crystal with patch twins on the right shoulder (grown at the US Air Force Research Laboratory, Hanscom AFB)

Fig. 7.2 Twin-free MLEK InP crystal (grown at the US Air Force Research Laboratory, Hanscom AFB) ◀

for twinning. Despite the controlled angle, *patch* twins are visible on the shoulders. These twins are relatively benign, as most of the crystal remains usable.

Research at several laboratories has taken advantage of crystal shaping as a means to minimize the incidence of twinning [7.16]. Magnetically stabilized liquid-encapsulated Kyropoulos (MLEK) [7.17–19] growth is one such technique, where the crystal is grown with a flat top before initiation of pulling, in order to reduce the incidence of twins (Fig. 7.2). When pulling commences, the crystal has already reached full diameter, and the growth angle changes from perpendicular to parallel to the growth axis. At that moment the growth angle must pass through the critical range, but facet formation is reduced because thermal gradients near the periphery are steeper than at the center. This method relies on magnetic stabilization of the melt to suppress turbulent flows at the solid–liquid interface. Without the magnetic field, the flat top would become unstable because of perturbations due to the temperature fluctuations of natural convection.

It is worthwhile to note here a peculiar historical twist. The Kyropoulos method is named after Spyro Kyropoulos, a German scientist (1911–1967) who later emigrated to the USA. His technique for growth of large alkali halide crystals was conceived to avoid the cracking problems arising from container growth [7.20]. The Kyropoulos method was further developed during the 1930s and 1940s by several groups to grow large optical crystals of alkali halides for spectroscopy. Until World War II (WWII), it was considered to be one of the leading techniques for growing large single crystals. In a survey of crystal growth techniques from 1930 to 1946, Wells [7.21] referred to only three general methods for obtaining single crystals: Bridgman growth, Kyropoulos growth, and solid-state recrystallization. The Czochralski method was not considered as a method for large crystal growth. Nevertheless, after WWII when germanium and silicon crystal growth were demonstrated at Bell Labs and Texas Instruments, the name of the new process was assigned to Czochralski. Coincidentally, the language of science was shifting at that time from German to English, a fact that may explain the misunderstanding. Because of this historical twist, some clarification is in order to distinguish

Fig. 7.3 Schematic diagram of a magnetic crystal growth furnace ◀

the two techniques. The main distinction is the pronounced difference between the crystal shapes, and the consequent differences between the curvatures of the solid–liquid interface. With the Kyropoulos method, the crystal forms an ellipsoid of rotation with its center deep in the melt. On the other hand, with the sloping shoulders of Czochralski growth, the solid–liquid interface is flatter.

7.2.3 Apparatus for Magnetically Stabilized Crystal Growth

The schematic diagram in Fig. 7.3 shows the basic components required for MLEC or MLEK growth. This custom furnace design was realized and is now in operation at the author's laboratory. Positioned around the outside of the growth chamber is a large Helmholtz

coil consisting of two toroidal magnets to provide an axisymmetric field up to 0.4 T. The two coils may be operated in tandem to provide an axial field, or in opposition to provide a cusped field. For a cusped field, the north pole of one coil points in the opposite direction to the other. The growth chamber is fabricated from nonmagnetic stainless steel to minimize screening losses and to allow the magnetic field to interact with the molten semiconductor. The water-cooled chamber is designed to operate at 20–40 atm ambient pressure. The upper chamber can be raised to allow access to the seed rod and a phosphorus ampoule. The upper chamber is separated by an isolation valve from the lower chamber, so that the phosphorus ampoule can be removed after in situ compounding of InP is completed. A seed is then attached to the seed rod, which can then be lowered into the growth chamber for crystal growth.

7.3 Magnetic Field Interactions with the Melt

The choice of magnetic field configuration and crystal shape are two types of engineering controls that can be exploited to improve the quality of InP crystals, with respect to twins, dislocations, and striations. In this chapter, the properties of InP crystals grown using these engineering controls are evaluated by synchrotron white-beam x-ray topography (SWBXT), chemical etching, and photoluminescence. Other controls, such as thermal gradient control and vapor pressure control, involving hardware modifications to the hot zone, are also considered for their practical application.

7.3.1 Hydrodynamic Principle

Although realizable magnetic flux densities are not large enough to eliminate melt motion altogether, a moderate magnetic field of 0.1–0.3 T can be used to tailor the melt motion for practical control of the crystal growth process. There are infinitely many ways to tailor the strength and configuration of the externally applied magnetic field, as well as the rotation rates, distribution of heat flux into and out of the melt, etc., so that models to accurately predict the system behavior are needed for process optimization. *Hurle and Series* [7.23] and *Walker* [7.24] reviewed the literature on the use of magnetic fields during bulk growth of semiconductors. Various components of fluid flow in InP melts have been modeled: melt-depletion flow [7.22], forced convection resulting from the rotational effects of the crystal and

crucible [7.25], and natural buoyant convection [7.26]. A global model combining the effects of pressure, thermal flux, magnetic field, and stress in the crystal was developed by *Zhang and Prasad* [7.27, 28]. The characteristic velocity U_c of melt motion in the magnetically

Fig. 7.4 Average melt velocity as a function of applied axial magnetic field and Hartmann number, calculated from the model of [7.22]. The shaded area shows the range where EM damping is sufficient for effective crystal growth control

damped melt is a critical indicator of EM suppression. This is shown graphically in Fig. 7.4, where calculated values of the average velocity are plotted against the Hartmann number [7.26]. The shaded area is the region where practical values of the magnetic flux can be used to control crystal shape and doping concentration for a given crucible design.

7.3.2 Effect of Magnetic Field on Crystal Twinning

The appearance of growth twins during the bulk crystal growth of InP is a recurrent yield-limiting problem. Because of their low stacking fault energy, indium-containing III–V compounds such as InP and InSb may have a higher tendency to form twins than other zincblende crystals. However, the general problem of twins in III–V crystal growth has been studied by experimentalists for many years [7.31, 32]. The first full theoretical treatment of twinning in III–V compound semiconductors was offered by Hurle in 1995 [7.29]. He observed that there were certain conditions under which internal (111) edge facets could be anchored to the three-phase boundary (TPB) at the solid–liquid–encapsulant interface. In addition, the appearance of an external shoulder facet coincides in many instances with the point of internal (111) facet anchoring. A diagram of the Hurle model in Fig. 7.5 shows the shouldering angle α and the angle ν between the edge facets and the extension of the crystal surface.

From a calculation of thermodynamic conditions for each orientation, Hurle derived a range of shouldering angles for which twinning was likely to occur. The model compared the undercooling at a high-index high-surface-energy external facet with that of a low-index low-surface-energy facet to determine if formation of a twin nucleus was energetically favorable. Hurle used this approach to predict the most dangerous shouldering angles for several zincblende crystals, including InP grown in the $\langle 001 \rangle$ and $\langle 111 \rangle$ directions. An experimental verification of this model was later published [7.33], where modifications to the Hurle theory were reported. These modifications were based on direct observations of the nucleation of twins on edge facets anchored to the TPB in S-doped MLEC-grown $\langle 001 \rangle$ InP single crystals using SWBXT and optical microscopy.

Undercooling at a facet during crystal pulling is determined by the nucleation process for a particular crystal face. Brice [7.30] pointed out that, to a simple approximation, the temperature gradient G in the solid at the interface depends on the radius of the crystal. If the curve of the interface passes through any low-index face, a facet will develop with undercooling ΔT . The crystal diameter is reduced by a chord formed by the facet, reducing the radius by a small amount (dimension c). As shown in Fig. 7.6, the undercooling at the center of the facet is given by

$$\Delta T = Gc. \quad (7.4)$$

The growth rate at the facet is controlled by this undercooling. The geometric relation between the facet half-width w and the temperature gradient can then be derived as

$$w^2 = c(2R - c), \quad (7.5)$$

Fig. 7.5 Diagram showing the attachment of an internal edge facet to the three-phase boundary (TPB) (after [7.29])

Fig. 7.6 Cross section (viewed from an angle slightly above the melt) schematic of a crystal with a shoulder facet (after [7.30])

and since the value of $R \gg c$ we can combine (7.3) and (7.4) to get

$$w^2 = \frac{2\Delta TR}{G}. \quad (7.6)$$

For a given crystal radius and a fixed growth rate, the undercooling is proportional to the square of the facet size. As the crystal diameter increases, so will the facet size, unless the undercooling is too small to sustain the facet. If undercooling is too large, the system becomes inherently unstable, and seeks a lower free energy.

In verifying the predicted relationship between twinning and growth angle, several [001] InP crystals were grown by the author with various shoulder angles from a 35° sloped shoulder to a 90° flat top. The incidence of twinning is generally higher in S-doped crystals than in crystals grown with other dopants, further motivating an investigation of the twinning defect. Study of the twins in these crystals by visual observation reveals a familiar pattern. Two kinds of twins exist: *patch twins*, which grow like epaulets on the shoulder, and *standard twins*, which grow on {111} planes passing through the boule center. Both types of twins nucleate on [110] ridge lines, but the patch twins are somewhat more benign in terms of wafer yield because they soon grow out of the crystal. A trend was observed after studying many crystals: twinning seems to occur more often on broad-shouldered crystals, but not so frequently on either low-angle shoulders or flat-top

crystals. However, these experiments show a marked difference in twinning probability depending on the field configuration.

Axial Field Growth

Magnetic stabilization using an axial magnetic field is a useful engineering control for controlling the InP growth process. As illustrated in Fig. 7.4, the melt velocity is reduced by an order of magnitude with an applied field of 0.2 T. Because of melt stabilization, dopant incorporation is more uniform, and shape control becomes reproducible. From the point of view of doping uniformity, it was possible to determine the effect on the solute boundary layer by comparing magnetically stabilized growth and standard LEC growth of InP [7.17]. To test the effect of magnetic fields on interface shape and dopant uniformity, two tin-doped crystals were grown, one without an applied magnetic field, and the other with an axial field of 0.2 T. Both were grown from melts weighing about 1 kg with tin concentrations of $5 \times 10^{19} \text{ cm}^{-3}$. After growth, these crystals were sliced into samples representing by weight each fraction of the grown crystal. The slices were then analyzed by glow-discharge mass spectrometry (GDMS). A plot of the tin concentration versus fraction grown was used to determine the effective distribution coefficient k_{eff} for each process. A comparison of the axial doping profiles revealed that k_{eff} is 2.5 times closer to unity for the magnetically stabilized growth. The

Fig. 7.7 A map of magnetic field strength for axial and cusped fields inside the crystal growth chamber at constant power

difference in k_{eff} indicates that static magnetic fields increase the boundary-layer thickness δ at the melt–solid interface. Considering the Burton, Prim and Schlichter (BPS) analysis in (7.3), one can see that k_{eff} is an exponential function of δ , since the growth rate R was the same in both cases, and the value of diffusivity D_L is assumed to be independent of the applied magnetic field. Using this analysis, the boundary-layer thickness is found to be 3.5 times larger for 0.2 T axial magnetic field growth compared with standard LEC growth.

Figure 7.7 shows the measured field strength within the chamber for cusped and axial fields. The axial field with aligned magnet pairs produced the highest magnetic field in the z -direction. Vertical scans were measured at the chamber center, and at 6.5 cm away from the center. The opposed magnet fields were measured in both the radial and axial directions. At the center, the vertical component B_z was zero, but small magnetic fields were measured at positions offset either vertically or radially.

Time-dependent temperature fluctuations in the melt were recorded with a sapphire optical thermometer and two thermocouples to reveal the effect of an axial magnetic field configuration on turbulent flow. For these measurements, the sensors were placed near the center of the melt at 2 and 12 mm from the crucible bottom (total InP depth approximately 31 mm and melt diameter 95 mm) with no crucible rotation. After the temperature reached steady state the magnet power was turned on and the field remained constant at 0.2 T. Figure 7.8 shows the off–on transient thermal behavior for the axially aligned field, where the temperature near center the

Fig. 7.8 Transient temperature fluctuations with no axial magnetic field ($t < 0$), and after axial magnetic field is turned on ($t > 0$)

Fig. 7.9 SWBXT transmission topograph of (110)InP:Sn cross-sectional slice showing dislocations and darker slip bands but no edge facets or striations. $g = 004$, $\lambda = 0.5 \text{ \AA}$, scale: crystal diameter = 55 mm

drops rapidly to a 20 °C lower level and remains steady with minor fluctuations.

A topograph of an InP:Sn crystal grown under an axial magnetic field is shown in Fig. 7.9. Here the conical growth angle is $\alpha = 82^\circ$, and the presumed angle ν would be 115° if there were edge facets attached to the TPB. Technically, the angle ν is the angle between the (111) edge facets and the extension of the crystal surface, as defined in Fig. 7.5. In this case there are no edge facets to be seen either by x-ray or by infrared (IR) topography. Both iron- and tin-doped crystals were grown without twins in the axial magnetic field using the flat-topped configuration.

Cusped Field Growth

For InP growth in a cusped field [7.34], the magnetic stabilization effect is much weaker. Since the two magnets are opposed, much of the field strength is canceled, and in fact the axial field goes to zero at the center. Although the radial component of the magnetic field is about 0.1 T, this is not strong enough for convective damping. Without a strong applied magnetic field, random oscillatory flow still exists in the melt, and flat-top growth is not possible because of twin formation or dendritic growth. In order to obtain a single crystal under these conditions, the crystal must be pulled as in LEC growth, i. e., avoiding the critical 74° cone angle. A few crystals were successfully grown in this fashion, but with occasional twin formation. The appearance of (111) edge facets attaching to the TPB are observed in IR transmission micrographs, as shown in Fig. 7.10. A twin line extends from one of the smaller facets at the shoulder.

Fig. 7.10 Nomarski micrograph of the shoulder of an InP crystal grown in a cusped field, showing edge facets attached to the TPB and a twin line parallel to the (111) plane

A measurement of the transient temperature behavior in a cusped field shows only a small effect on turbulence at the moment when the magnet is turned on. Using the same temperature sensors as described above, time-dependent temperature fluctuations were recorded, again with no crucible rotation. After the temperature reached steady state the magnet power was turned on and the field remained constant at 0.2 T. Figure 7.11 shows the off-on transient thermal behavior for the cusped field, with opposed magnets. There is no discernible change in the temperature near the center, and a slight increase near the crucible edge. Thermal fluctuations are reduced by $\approx 25\%$ in amplitude, with more

Fig. 7.11 Transient temperature fluctuations before ($t < 0$) and after ($t > 0$) cusped magnetic field is turned on

regular frequency, and there is a slight shift in average temperature.

Examination of the growth striations by IR transmission microscopy revealed some interesting differences between the axial and cusped magnetic fields [7.34]. For flat-topped crystals grown under axial field conditions, regular striations were observed which appeared to follow the rotational frequency. Calculating the rotational growth period by dividing the growth rate by the rotation rate gives $V/R = 50 \mu\text{m}$ as the length per rotational period. The observed striations showed a regular spacing corresponding to approximately $50 \mu\text{m}$. No facets were observed to be anchored to the TPB.

On the other hand, crystals grown in a cusped field exhibited a random striation pattern (Fig. 7.10), with striae periods as small as $30 \mu\text{m}$ and as large as $150 \mu\text{m}$. A large variation from center to edge was also observed, indicating that the interface shape is locally variant. Edge facets on (111) planes were observed near the top surface of the crystal, coinciding with the plane of twin formation.

The interface shape was examined with infrared transmission images taken with the IR camera for the two different magnetic configurations. For axial field growth the interface was convex at the seed end (radius of curvature $r = 5 \text{ cm}$). On the other hand, for crystals grown with a cusped field, the interface shape is sigmoidal, i. e., convex with a radius of 9 cm and deflected edges.

Figure 7.12 shows a detail from a scanned SWBXT image, recorded in transmission Laue geometry, from a (110) wafer cut from a S-doped, [001]-grown InP single crystal in which a twin was formed in a region where ($\bar{1}\bar{1}$) edge facets came into contact with the external shoulder of the crystal (i. e., were anchored at the TPB during crystal growth). On the right-hand side of this image a twin nucleates in a region containing anchored edge facets at the point where the shoulder angle reaches 74.21° . When viewed from above, a ($\bar{1}\bar{1}5$) external shoulder facet appears on the shoulder at the same point. After twinning, this ($\bar{1}\bar{1}5$) facet is replaced by a ($\bar{1}\bar{1}1$) facet. In this experiment, the external shoulder facets present before and after twinning were precisely identified using synchrotron white-beam back-reflection spot patterns [7.33].

Considering the left-hand side of this image, we observe anchored edge facets in several regions of differing shoulder angle, but none close enough to 74.21° to enable the creation of the ($\bar{1}\bar{1}5$) external shoulder facet required for the nucleation of a twin. Consequently no twinning is observed in this region, a confirmation

Fig. 7.12 SWBXT image recorded in transmission Laue geometry ($g = 004$, $\lambda = 0.45 \text{ \AA}$) showing the shoulder region of crystal. E indicates anchored edge facets. Local shoulder angles are indicated

of the importance of shoulder geometry. In the same boule, twinning was also observed to occur on the $(\bar{1}\bar{1}\bar{1})$ planes, leading to the conversion of a $(\bar{1}\bar{1}\bar{4})$ external shoulder facet to a $(\bar{1}\bar{1}0)$ one. In this case the twin, although nucleated in the shoulder region, grows out of the crystal. The local shoulder angle, in this case, must become equal to 70.53° , i.e., the shoulder must be parallel to $(\bar{1}\bar{1}\bar{4})$. Again, the presence of the various shoulder facets in the actual crystal was confirmed using synchrotron white-beam back-reflection spot patterns.

The concept of facet conversion resulting in a lower free energy is consistent with the Hurle model, but the model was modified by the authors [7.33] to agree with the observed geometry. For twinning in $\langle 001 \rangle$ growth of InP, the most dangerous shouldering angle was changed from 35.5 to 74.21° ; and the range of shoulder angles over which edge facets are thermodynamically favored to be anchored to the TPB was changed from $31^\circ < \nu < 86.5^\circ$ to $31^\circ < \nu < 112^\circ$, as illustrated in Fig. 7.13. A significant reduction in the estimated undercooling required to promote twinning was changed from ≈ 15 to $\approx 2^\circ\text{C}$.

Fig. 7.13 Diagram of facets at TPB and a twin at the most likely growth angle for twin formation

Polarity of Twinning

Since the twin plane in InP is the polar $\{111\}$ family of planes, another important factor to be considered is the polarity of the observed twin planes. The question is: of the two types of edge facets, either $\{111\}_M$ or $\{\bar{1}\bar{1}\bar{1}\}_P$, anchored to the three-phase boundary, which has the higher propensity for generation of twins? Choosing the polarity of the seed face which is in contact with the melt in order to avoid twinning in $\langle 111 \rangle$ -grown InP has long been recognized [7.32]. However, an understanding of the influence of polarity on facet formation and twinning is not available for all zincblende structure crystals. In particular such understanding is lacking for InP.

In order to study the influence of polarity on faceting and twinning, it is important to be able to determine polarity unambiguously. Traditional practice has been to use chemical etching to distinguish between the two polar opposite faces of $\{111\}$ InP. The etching behavior of the In and P faces of InP are clearly different, but questions have been raised as to which surface is P- or In-terminated. Mullin et al. [7.35] report on the use of $6:3:1$ and $6:6:1 \text{ H}_2\text{O}:\text{HNO}_3:\text{HCl}$ in order to distinguish P faces from In faces in InP. Bachmann and Buehler [7.36], using the opposite indexing convention, confirm the usefulness of the $6:6:1$ etch in producing etch pits on the In face to discriminate between polar faces.

An experiment to confirm the etching method and to determine the crystallographic polarity of the $\{111\}$ edge facets by x-ray anomalous scattering was reported by Dudley [7.37]. To generate significant anomalous scattering for the case of InP, a characteristic radiation with a wavelength close to the In absorption edge ($\lambda_K = 0.444 \text{ \AA}$) was used. In this SWBXT study, plots of diffracted intensity as a function of Bragg angle corresponding to the $(\bar{1}\bar{1}\bar{1})$ and $(\bar{1}\bar{1}\bar{1})$ reflections, and also a plot of the ratio of the intensities of these reflections, were used to verify the etching results (Fig. 7.14a,b).

It can be seen that, for both reflections, the diffracted intensity changes abruptly at the absorption edge due to the drastic variation of the absorption coefficient. More important, the intensity values of the two reflections are significantly different in the vicinity of the absorption edge. The calculated ratios $|F_{111}^P/F_{111}^{\text{In}}|^2$ and $|F_{111}^P/F_{111}^{\text{In}}|$ are also shown in Fig. 7.14. These two curves represent the theoretical diffracted intensity ratios according to the kinematical and dynamical x-ray diffraction models, respectively. One would expect that, for a single crystal containing defects, the diffraction generally would contain both dynamical and kinematical contributions. It can clearly be seen that the profile of the ratios of the measured intensities is similar in shape to the theoretical predictions. Therefore, synchrotron x-ray anomalous scattering shows unambiguously that $(1\bar{1}1)$ is a P face while $(\bar{1}\bar{1}\bar{1})$ is an In face. These results are consistent with etching figures from either Br/methanol or 6:6:1 etchants that produce a smooth surface on the P face, while producing triangular pits on the In face.

With the polarity of $(1\bar{1}1)$ and $(\bar{1}\bar{1}\bar{1})$ being unambiguously defined, we can now define the polarity of the twins in InP, to say that twinning is observed to nucleate on only $\{1\bar{1}\bar{1}\}_P$ facets. Quite clearly, the preference for twinning on $\{1\bar{1}\bar{1}\}_P$ facets is related to the high incidence of twinning observed by Bonner [7.38] when growing InP in the $[111]_{\text{In}}$ direction. The preferred seed orientation is with the P face in contact with the melt. Similar results were reported by Steinemann and Zimmerli [7.39] for GaAs, which exhibited a preference for twinning on $\{\bar{1}\bar{1}\bar{1}\}_{\text{As}}$ planes. The effect of seed polarity on twinning incidence could be accounted for if the surface energy of the In-terminating facet was significantly higher than the P-terminating one. Hurle [7.29] cited the results of the model calculations of Oshcherin [7.40], who reports a value for the surface energy of the Ga-terminating facet that is $\approx 12\%$ higher than that of the As-terminating one. Surface energy values were reported by Oshcherin also for InP. Calculated values of the surface energy of $\{111\}_{\text{In}}$ faces were reported to be more than 30% larger than those for $\{1\bar{1}\bar{1}\}_P$ faces.

Twinning Summary

As a result of these studies, we have a better understanding of the fundamental causes of, and methods to control, twinning in InP crystal growth. Specifically, the magnetic field configuration, the dopant species, and the conical growth angle are three important parameters

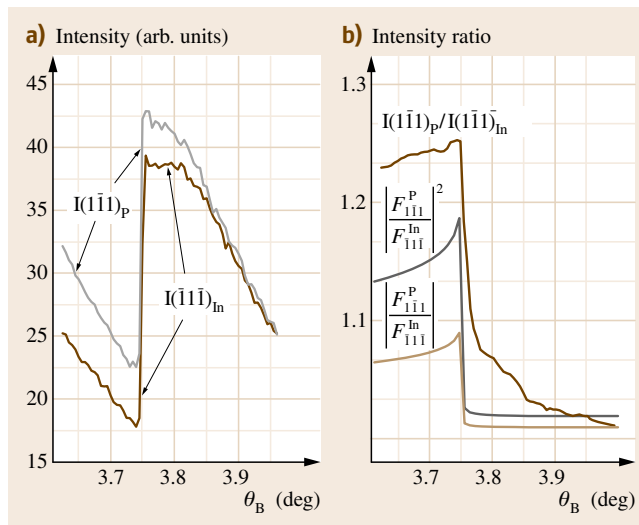

Fig. 7.14a,b Plots of (a) observed intensity versus Bragg angle plots for the two reflections, and (b) observed ratios of diffracted intensity as a function of Bragg angle from the $(1\bar{1}1)_P$ and $(\bar{1}\bar{1}\bar{1})_{\text{In}}$ planes, and calculated ratios of diffracted intensity according to kinematical theory, i.e., $|F_{111}^P/F_{111}^{\text{In}}|^2$ and dynamical theory, i.e., $|F_{111}^P/F_{111}^{\text{In}}|$

for control of twinning. Trade-offs can be made among these variables to minimize the occurrence of twins.

Although there are many possible causes of twinning in InP, two major causes which can be influenced by engineering controls are:

1. Uncontrolled crystal shape. In shaping the crystal from a narrow seed to a full-diameter body, the conical growth angle is a function of the imposed thermal gradient and the crystal pulling rate.
2. Sudden perturbations in the melt. Because InP crystals are grown with the encapsulant surface exposed to high pressure, temperature gradients in the liquid are steep (50–110°/cm). Uncontrolled oscillatory flows can cause severe thermal perturbations in the melt, resulting in rapid changes in the solid–melt interface shape.

The modified Hurle model, which predicts the incidence of twinning in the growth of III–V semiconductor compounds, focuses on uncontrolled shape as the primary cause of twinning. However, this is not the only factor in controlling twin nucleation in InP. The choice of dopant and magnetic field configuration are also

important. A comparison between the theoretical predictions of the incidence of twinning and experimental observation of the incidence of twinning in MLEC-grown [001] InP reveals the following:

1. X-ray topographic observations, etching studies, and IR transmission microscopy revealed the occurrence of twins nucleated at {111} edge facets anchored to the TPB. For (100) seeded InP crystals, this condition is most likely to occur when the angle ν between the edge facet and the extension of the crystal surface, falls in the range $31^\circ < \nu < 112^\circ$. For crystals grown with the angle $\nu > 112^\circ$ in which edge facets do not appear to be attached to the TPB, twin-free crystals can be grown by using the axial magnetic field configuration.
2. The conical growth angle α where twinning is most likely is 74.2° , where a {115} external shoulder facet is converted to a {111} shoulder facet. The most favorable angle for conical growth is 35.3° , where diagonal twins are minimized, for (100)-oriented InP crystals. However, this angle allows the possibility to produce patch twins. At a growth angle of 35.3° , the dominant {111} matrix facets typically appear on the crystal shoulders and these facets are favored because of their low surface energy. On the other hand, at a growth angle of 74° , the $\{115\}_M \rightarrow \{111\}_T$ transformation follows exactly the crystallographic orientation relationships of 180° rotation twins. In other words, a {111} external facet would be introduced by twinning if the external surface of the growing crystal becomes parallel to a {115} lattice plane just prior to twinning.
3. Of all the impurity elements used as dopants in this series of experiments, sulfur appears to be the most likely to cause twins. S-doped crystals also exhibit large shoulder facets during growth, an indication that sulfur doping increases undercooling. Other dopants, such as tin, even at the same high concentration, are not as likely to cause twinning.
4. The axial magnetic field configuration is preferred over the cusped field for controlling twins. With the axial field, there are more options to take advantage of crystal shaping as a means of reducing twins. However, because of the increased radial thermal gradient, the axial magnetic field increases thermal stress in the crystal.
5. Close examination of {110} cross-sectional views of S-doped InP crystals reveals that the edge facets may actually increase and then decrease in size before twinning nucleates, suggesting that a critical undercooling may not control the twinning process. Rather, the critical point at which the twin nucleates seems to be associated with production of the {115} shoulder facet, which upon twinning, converts to a {111} shoulder facet.

7.4 Dislocation Density

The primary cause of the high dislocation density in pulled crystals of InP is thermoelastic stress during crystal growth. A high density of dislocations can degrade the performance of photodetectors [7.41] and it affects the properties and performance of many other InP-based devices [7.42]. Dislocations may also change the mechanical properties of InP and contribute to point defect and impurity migration [7.43]. To reduce the dislocation density, sulfur doping is a preferred method, because of its lattice-hardening effect. The need for crystals with low dislocation density is increasing, because these structural defects can limit the performance of advanced monolithic microwave integrated circuits (MMICs) and optoelectronic integrated circuits (OEICs).

High dislocation density is less of a problem with vertical gradient freeze (VGF) or vertical Bridgman (VB) crystals, where the temperature gradient is signif-

icantly reduced compared with LEC growth. Densities of less than 500 cm^{-2} are generally reported for VGF crystals. Thermoelastic stresses are lower in the vertical configuration of container growth because the temperature gradients are so low. Thermal gradients at the solid-melt interface are on the order of 10–15 K/cm in the VGF process, very low compared with typical LEC growth at 60–80 K/cm or higher. For pulled crystals, the steep temperature gradient is the price one must pay to provide stability to the crystal growth environment. Without such steep gradients, diameter control is more difficult, twinning probability is increased, and surface decomposition occurs as the crystal grows out of the encapsulant.

Despite conditions of very steep thermal gradients, for Czochralski silicon growth it is possible to grow large crystals that are virtually dislocation free because the use of *Dash* [7.44] seeding eliminates dislocations

Table 7.1 Results of dislocation reduction experiments

Crystal/ dopant	Seeding condition	Growth rate (mm/h)	Clearance length (mm)	Interface shape	Mechanism	Origin of dislocation
InP:S crystal A	Hot seed	0–27	12	Convex	Glide	Stress induced
InP:S crystal B	Cold seed	0–54	18	Convex	Glide	Stress induced

that emanate from the seed. For InP growth, a similar technique [7.45] demonstrated that dislocation-free InP could be grown, but only up to 15 mm in diameter. When the diameter exceeds that, dislocations are generated at the periphery of the boule (not from the seed) due to the combination of tensile stresses and defects forming at the crystal surface. Reducing the density of dislocations in InP has been the subject of considerable effort during recent decades. The question has been raised of how best to reduce or minimize dislocation generation during InP bulk growth. One approach is the combination of magnetic field stabilization to reduce random thermal fluctuations together with Dash seeding to reduce dislocations from the seed.

7.4.1 Dislocation Reduction During Seeding

In principle, the formation of new dislocations within a crystal under normal growth conditions is nearly impossible. Stresses approaching the shear modulus (10–70 GPa) would be required to generate a new dislocation in the bulk. Thermoelastic stress during InP crystal growth rarely exceeds 10 MPa, and yet the dislocation density in pulled crystals is often greater than $5 \times 10^4 \text{ cm}^{-3}$. This has led many to assume that all dislocations are generated from the seed. If this is true, a seeding technique that removes the grown-in dislocations could result in defect-free single crystals. A controlled seeding test for InP crystal growth was employed [7.46] to suppress the propagation of dislocations from the seed–melt interface. This study showed how the strategy of necking can be exploited to effectively eliminate dislocations in MLEC InP. Dislocations formed at the seed–melt interface are seen to glide out of the neck region. Understanding this mechanism of dislocation reduction in InP crystal growth may lead to better control of dislocation formation and migration. This study showed the origin of the dislocations to be induction by thermal stress rather than by replication of dislocations growing directly from the seed. The results of the experiments are tabulated in Table 7.1.

One source of dislocations is generated at the seed–crystal interface, and these dislocations may propagate through the crystal. The Dash seeding approach, discovered in 1958 [7.44], increases the pulling rate of the narrow neck until a defect-free condition appears. Dash speculated that dislocations leave the crystal, in the necked region, due to climb caused by vacancy supersaturation. One difference between compound semiconductors and silicon may be the mechanism of dislocation formation. In the case of Dash’s silicon model, the dislocations are grown in at the solid–liquid interface and propagate along the growth direction until they move out of the narrow neck by the climb mechanism. On the other hand, for InP there is no evidence of straight-line axial dislocations; rather, it appears that segments of dislocations from the seed are threading into the newly grown crystal. The dislocations arise from stress in the solid, and they propagate

Details of the mechanism leading to dislocation density reduction during necking were revealed, and the strategy of necking as an effective means to eliminate defects in InP was exploited. The effectiveness of the necking process as a strategy for reducing the dislocation density in MLEC-grown InP crystals was discussed.

Figures 7.15 and 7.16 show scanned transmission topographs recorded from two (110) InP slices. Figure 7.17 shows a geometric sketch of the dislocations in both crystals. Sample A (Fig. 7.15) has a narrow neck, whereas sample B (Fig. 7.16) expands in diameter from the seed. These crystals formed different shapes due to different growth conditions during initial seeding. For sample B, the initial temperature was slightly colder than normal – a condition called a *cold seed*. In contrast, the initial melt temperature for sample A was higher, and the meniscus diameter was smaller; this is called a *hot seed*. As the temperature was reduced, solidification proceeded to move down the narrow meniscus until the diameter started to increase. Comparing these two samples with different shapes, it

by slip-induced glide along the closest-packed {111} planes.

Bliss et al. [7.46] demonstrated crystal growth with a controlled seeding technique that suppressed the propagation of dislocations from the seed-melt interface.

Fig. 7.17 Geometric sketch of the dislocations in both sample A and B

Fig. 7.18 SWBXT transmission topograph of sample A, a (110) slice of InP:S seed-neck region, with $g = 004$. *Inset*: Nomarski image of the etched surface around the twin lamella

is possible to evaluate the effectiveness of the necking process.

The diffraction vector for both topographs in Figs. 7.15 and 7.16 is $4\bar{4}0$, and the radiation wavelength is about 0.48 \AA , slightly larger than the indium K-absorption edge (0.44 \AA). In the figures the seed-crystal interface is represented; D_1 and D_2 are two groups of dislocations lying on $(1\bar{1}1)$ and $(\bar{1}11)$ planes, respectively. D_3 are dislocations lying on $(11\bar{1})$ planes, which are 35° from the (110) surface. A twin lamella intersects the surface in Fig. 7.15, bounded by two D_3 clusters, as can be seen more clearly in Fig. 7.18, the 004 topograph of sample A. By analyzing the projection lengths of the short, straight segments of D_3 dislocations, it was determined that they are parallel to the $(11\bar{1})_p$ twin plane. The dislocation density in the D_3 clusters is higher even than the dislocations in the seed (above $2 \times 10^4 \text{ cm}^{-2}$), so that individual dislocations cannot easily be resolved. The D_3 dislocation cluster indicates that there is plastic deformation along the twin plane. Thus, the dislocations are channeled by the twin lamella. The subsequent stress upon cooling is relaxed by the growth of D_3 clusters of dislocations adjacent to the twin lamella.

Most of the dislocations appear as intermittent short lines in both samples. The angles between the dislocation lines and the $[00\bar{1}]$ growth direction are about 35° . In Fig. 7.17 the dashed lines represent the cross-sectional shape of sample A while the solid lines correspond to sample B. A_1 and A_2 are two lines drawn from the bottom edges of the seed, at 35° to the growth axis. Most of the dislocations are distributed in the region of crystal above the lines A_1 and A_2 . Below this

region, very few dislocations can be found. Such dislocation configurations have been reproducibly observed in almost all MLEC-grown necked InP crystals. This demonstrates that these dislocations are closely related to the seed-crystal interface.

7.4.2 Analysis of Dislocations

In order to characterize the Burgers vector of the dislocations observed, transmission topographs with various diffraction g vectors were taken. Figures 7.19 and 7.20 show enlarged topographs near the seed-crystal interface of sample A, where the diffraction vectors are (a) $3\bar{3}3$ and (b) $3\bar{3}\bar{3}$. For the topographs in Figs. 7.19 and 7.20, some of the dislocations disappear because of the extinction conditions

$$\begin{aligned} \text{Screw: } & g \cdot b = 0, \\ \text{Edge: } & \begin{cases} g \cdot b = 0, \\ g \cdot (b \times l) = 0, \end{cases} \end{aligned} \quad (7.7)$$

where b is the dislocation Burgers vector and l is the dislocation line direction.

The extinction conditions for D_1 and D_2 dislocations are summarized in Table 7.2. From the extinction criteria of dislocation contrast on x-ray topographs [7.47], it can be determined that both D_1 and D_2 are segments of dislocations with mainly screw character. As shown in Table 7.2, D_1 can be explicitly determined as composing the dislocations with the line directions of $[011]$ and $[10\bar{1}]$ and Burgers vectors $\frac{1}{2}[011]$ and $\frac{1}{2}[10\bar{1}]$, respectively. In the case of D_2 , the

D ₂	004, 440, 422 etc.	333, 242	(111) ₂ ¹ [101]
	004, 440, 242 etc.	333, 422	(111) ₂ ¹ [011]

dislocation lines are mainly along [101] and [011] with Burgers vectors of $\frac{1}{2}[101]$ and $\frac{1}{2}[011]$, respectively.

Unlike Dash’s straight axial growth dislocations, which originate in the seed, the topographs presented here show dislocations that consist of short segments lining up on three {111} planes. Careful observation of the spatial distribution and projected directions of these short dislocation segments, as determined above, confirms that they cannot be traced directly back to the seed, and therefore they cannot be growth dislocations. In addition, dislocation half-loops, indicating glide processes, can be observed in the topographs. These half-loops contain segments with line directions that are either parallel to the growth front or curve back against the growth front, which cannot occur if the dislocation is a growth dislocation [7.48]. It is thus apparent that most of the dislocations observed in these samples are not growth dislocations but are generated by postgrowth plastic deformation, i.e., by dislocation movement or interaction following crystal growth (behind the growth front). This is not surprising, considering the stresses generated due to the steep temperature gradients during MLEC growth. These straight segments of dislocations with mainly screw character

are the remnants of dislocation loops generated via the stress-induced multiplication of dislocation segments from the seed, which thread into the newly grown region of crystal. As is common in crystals with the zincblende structure, the velocities of edge dislocations are greater than their screw counterparts. Consequently, rapidly moving edge segments, which in this case escape through the outer periphery of the necked region, may leave behind a remnant of trailing screw segments. The dislocation loops will expand in such a fashion that the screw segments will enlarge laterally as well as extending their lengths. Therefore, the screw segments may not be directly traced back to the seed interface. No clear evidence is found supporting the conjecture of Dash [7.44] that the reduced dislocation density resulting from the necking process is associated with the climb-induced motion of dislocations.

These experiments demonstrate that most of the dislocations in MLEC-grown InP crystals originate from the seed–crystal interface, propagate via slip processes on {111} planes, and eventually exit the crystal through the periphery of the necked region. It is apparent that one can effectively limit the dislocation regions by choosing proper growth conditions, i.e., by adopting the necking technique. At least for small-diameter crystals, a pyramid-shaped sector which is nearly dislocation free is formed below the dislocation regions. However, the defect-free region cannot be successfully expanded as the crystal grows to full diameter. New dislocations are observed at the periphery as the crystal diameter increases. These dislocations are clearly not generated from the seed, but rather they seem to be propagating from the outer edge where faults exist at the shoulder surface.

7.5 Magnetic Field Effects on Impurity Segregation

Incorporation of dopant impurities from the melt into the crystal is dependent on the applied magnetic field, as described in Sect. 7.2.2. The use of impurity doping requires control of uniformity on both the macroscale and microscale. The magnetic field has been shown to contribute to axial as well as radial uniformity. This is important because all of the commercial uses of InP material require impurity doping in the crystal. Unlike GaAs bulk material, where a native defect EL2 contributes the deep level responsible for semi-insulating electronic properties, in the case of InP the dopant impurity iron must be added to provide the deep-level defect. Iron is the only impurity species

that can compensate the residual shallow donors of InP to produce semi-insulating material with resistivity at least $10^7 \Omega \text{ cm}$. However, the distribution of iron in the crystal can have two possible negative consequences. Macrosegregation of impurities can lead to yield problems; if maximum solubility is reached, precipitate formation, or interface breakdown due to constitutional supercooling will occur. On the other hand, the microsegregation of impurities can lead to striations, especially pronounced in the case of sulfur doping. And for the case of iron, with a solubility limit of $3 \times 10^{17} \text{ cm}^{-3}$, at high doping concentrations the nucleation of precipitates becomes a problem.

7.5.1 Compensation Mechanism of InP:Fe

It is known that Fe substitutes for In in InP and primarily adopts the neutral Fe^{3+} state (so called to denote its oxidation state). However, some of the iron is compensated by shallow donors to form Fe^{2+} , and the ratio between the ionized and neutral concentrations, $\text{Fe}^{2+}/\text{Fe}^{3+}$ was shown [7.49] to vary linearly with the free carrier concentration n . A linear dependence of n on $\text{Fe}^{2+}/\text{Fe}^{3+}$ is expected since both quantities are proportional to the term in the Fermi distribution function $\exp[-E_F/(k_B T)]$, where E_F is the Fermi energy and k_B is the Boltzmann constant. The free carrier concentration can be expressed as

$$n \cong N_C \exp\left(-\frac{E_C - E_A}{k_B T}\right) \frac{[\text{Fe}^{2+}]}{[\text{Fe}^{3+}]} \frac{g(\text{Fe}^{3+})}{g(\text{Fe}^{2+})}, \quad (7.8)$$

where N_C is the density of states in the conduction band and g represents the degeneracies of the two iron defect states. The energy difference $E_C - E_A$ is simply the change in Gibbs free energy associated with the transfer of an electron from the occupied iron acceptor level to the conduction band. The Gibbs free energy can be expressed in terms of the enthalpy H and entropy S as $G = H - TS$. The above equation can then be rewritten as

$$n \cong N_C \exp\left(-\frac{H}{k_B T}\right) \exp\left(\frac{S}{k_B}\right) \frac{[\text{Fe}^{2+}]}{[\text{Fe}^{3+}]} \frac{g(\text{Fe}^{3+})}{g(\text{Fe}^{2+})}. \quad (7.9)$$

The slope of an Arrhenius plot of $\log n$ versus $1/T$ gives the change in enthalpy H or the activation energy extrapolated to temperature $T = 0$; this value of 0.63 eV is the same as that measured by temperature-dependent Hall effect or by deep level transient spectroscopy (DLTS). However, the entropy S can also be extracted to give the temperature shift of the iron acceptor level. Zach determined this value and found that the temperature shift was different from the temperature shift of the bandgap [7.49]. This is illustrated in Fig. 7.21, which shows the relative shift of the bandgap versus the deep defect level. The results indicate that the thermodynamic position of the $\text{Fe}^{2+}/\text{Fe}^{3+}$ level at room temperature is 0.49 eV below the conduction band, and it is this energy that determines the carrier concentration. For example, referring to (7.9), the room-temperature carrier concentration for a half-occupied iron acceptor level, $\text{Fe}^{2+}/\text{Fe}^{3+} = \frac{1}{2}$, would be $n \cong 10^9 \text{ cm}^{-3}$. In this circumstance, with Fe-doping levels even twice as high as residual shallow donors, at room temperature InP material is still conducting.

Fig. 7.21 Energy band diagram versus temperature for InP:Fe, showing the shift in bandgap energy (slope = $3.8 \times 10^{-4} \text{ eV/K}$) and the shift in the Fe acceptor ionization energy (slope = $4.7 \times 10^{-4} \text{ eV/K}$)

The Fermi energy can only be reduced to the mid-gap level as the occupancy of the iron acceptor level decreases, so that for $\text{Fe}^{2+}/\text{Fe}^{3+} = \frac{1}{10}$, the free carrier concentration will be $n \cong 10^7$. In other words, for typical semi-insulating InP with residual donor concentrations of $1\text{--}3 \times 10^{15} \text{ cm}^{-3}$, a minimum Fe doping level of $1\text{--}3 \times 10^{16} \text{ cm}^{-3}$ is required.

Zach [7.49] calculated the temperature shift of the iron level from the conduction band to be $-4.7 \times 10^{-4} \text{ eV/K}$. This value was later verified [7.50] by an optical experiment using two-wave mixing photorefractive and absorptive gain to evaluate the $\text{Fe}^{2+}/\text{Fe}^{3+}$ ratio in InP:Fe. As they varied the temperature of the crystal they observed that the wavelength of absorption gain was strongly dependent on temperature. For example, when the wavelength is fixed at 973 nm a null absorption gain is obtained at a crystal temperature of 285 K, while for a wavelength fixed to 991 nm a null gain is obtained at a crystal temperature of 330 K. The null point corresponds to the disappearance of the photorefractive space-charge grating because the creation of holes exactly compensates the creation of electrons ($\sigma_p p_{T0} = \sigma_n n_{T0}$). In this terminology, p_{T0} refers to Fe^{3+} and n_{T0} refers to Fe^{2+} . These results were explained by the temperature dependence of the iron level position as a function of temperature. That is, a shift of the iron level introduces a change in the optical cross sections. Using the temperature for which the absorption gain is null at $\lambda = 991$ and 973 nm, the temperature shift of the iron level with respect to the conduction band was found to be

$$\begin{aligned} \frac{dE_{\text{Fe-CB}}}{dT} &= \frac{E_{991 \text{ nm}} - E_{973 \text{ nm}}}{T_{991 \text{ nm}}^{I_a=0} - T_{973 \text{ nm}}^{I_a=0}} \\ &\approx -5.1 \times 10^{-4} \text{ eV/K}. \end{aligned} \quad (7.10)$$

This value is in close agreement with the value obtained by Zach. Significantly, the compensation model has been confirmed by both optical and electrical experiments.

7.5.2 The Role of Hydrogen

In semi-insulating InP material the concentration of ionized acceptors Fe^{2+} appears to be higher than the measured concentrations of Si and S. The donor impurities that compensate the iron acceptors in InP cannot all be accounted for through trace impurity analysis by glow-discharge mass spectroscopy (GDMS). Additional residual donors, not detected by impurity analysis, are present in these samples. It has been proposed that the other donor which contributes to the ionized Fe^{2+} concentration is hydrogen [7.52].

Several studies [7.53–55] of the absorption spectra of hydrogen in InP have established the structure of hydrogen-related complexes. The local vibrational mode (LVM) absorption at 2315.6 cm^{-1} in LEC InP shown in Fig. 7.22 is due to the P–H stretching modes in an environment that has tetrahedral symmetry [7.55]. Isotopic co-doping with deuterium and hydrogen was used [7.52] to investigate the LVM in InP. The splitting in the D–H spectrum was consistent with a defect having tetrahedral symmetry, and the authors proposed that the absorption is due to a fully passivated indium vacancy $[\text{V}_{\text{In}}(\text{PH}_4)]$. Investigation of the electrical prop-

Fig. 7.22 Infrared absorption spectra in the range of the InP:H LVM line before and after annealing (after [7.50])

Fig. 7.23 Infrared absorption spectra in the range of the Fe^{2+} intracenter absorption before and after annealing (after [7.51])

erties of the hydrogen defect in InP [7.56] showed that this defect has a characteristic donor behavior.

The $\text{V}_{\text{In}}\text{H}_4$ defect disappears during annealing at $\approx 900^\circ\text{C}$ under a phosphorus overpressure, as shown in Fig. 7.22. For undoped bulk InP a reduction in free carrier concentration and an increase in mobility after annealing is also observed, consistent with a decrease in the donor-related $\text{V}_{\text{In}}\text{H}_4$ defect. For the case of Fe-doped material, annealing experiments [7.51, 57] showed the role of hydrogen-related donors in controlling resistivity. In these experiments the Fe^{2+} absorption peak was measured quantitatively to determine the residual shallow donor concentration. For semi-insulating Fe-doped material, annealing reduces the Fe^{2+} absorption peak as seen in Fig. 7.23. The change occurs without any measurable increase in Fe^{3+} by diffusion or other mechanisms. How to quantify the effect of hydrogen in Fe-doped InP is the key to understanding the $\text{V}_{\text{In}}\text{H}_4$ defect – and crucial for producing semi-insulating InP with a minimum concentration of iron.

7.5.3 Annealing Experiments

It has become apparent in the last few years that post-growth thermal treatment can bring about modification of the intrinsic defect concentrations in InP crystals [7.58–63]. It is now understood that the conversion

Table 7.3 Effect of annealing and cool-down on Fe-doped InP samples

Sample cool-down procedure	[Fe ²⁺] (cm ⁻³) as grown	[Fe ²⁺] (cm ⁻³) annealed	Δ[Fe ²⁺] (cm ⁻³)	VH ₄ integrated absorption (cm ⁻²)
Slow cool	3.3 × 10 ¹⁵	1.5 × 10 ¹⁵	1.8 × 10 ¹⁵	0.089
Fast cool	3.3 × 10 ¹⁵	1.7 × 10 ¹⁵	1.6 × 10 ¹⁵	0.097

from n-type to semi-insulating behavior by annealing at $\approx 950^\circ\text{C}$ is a consequence of the escape of shallow donors (the VH₄ defect) and the presence of a residual concentration of iron. Some commercial vendors now offer undoped InP that is wafer-annealed under FeP₂ atmosphere to provide semi-insulating properties with high mobility [7.64]. Some questions still persist, however, concerning the precise mechanism of thermal conversion. Does high-temperature treatment annihilate the VH₄ defect complex, or does it merely stimulate the diffusion to free surfaces? Likewise, if iron atoms are *electrically active* only on substitutional In sites, what happens to the InP crystal when iron diffusion occurs through an interstitial mechanism? After annealing, are some iron atoms quenched into inactive interstitial sites? The annealing experiments discussed in [7.65] were designed to answer some of these questions.

In order to determine the activation behavior of iron, Fe-doped InP crystals were grown by the MLEC method, such that the total iron concentration ranged from 1×10^{16} to $1 \times 10^{17} \text{ cm}^{-3}$ from seed to tail. The conductivity type of these crystals was semi-insulating (i. e., with free carrier concentration $n < 2 \times 10^8 \text{ cm}^{-3}$). The crystals were cut into rectangular $1 \times 1 \times 2 \text{ cm}^3$ polyhedra. Optical absorption spectra in the range $500\text{--}3500 \text{ cm}^{-1}$ (60–300 meV) were measured with a Digilab 80E-V vacuum Fourier-transform spectrometer. Samples were mounted in an exchange gas optical cryostat and cooled to temperatures between 6.5 and 12 K. The highest instrumental resolution used was 0.125 cm^{-1} , and standard measurements were performed at 0.25 cm^{-1} resolution.

These crystals were annealed in quartz ampoules with sufficient phosphorus to provide an overpressure of 5 atm at 900°C , well above the equilibrium partial pressure of P over InP. After being held at 900°C for 36 h the samples were cooled either slowly or rapidly to room temperature. Slow cooling was performed at a rate of less than 1 K/min, whereas rapid cooling was in excess of 5 K/min.

The results of the annealing experiments can be summarized as follows: In the case of slowly cooled samples, measurements of the hydrogenated vacancy VH₄ from the integrated absorption at 2316 cm^{-1}

showed virtually complete annihilation of the defect after annealing. In these same samples, the Fe²⁺ absorption lines were measured before and after annealing. The results are tabulated in Table 7.3.

The reduction in the Fe²⁺ concentration after annealing is directly proportional to the reduction of integrated absorption due to the hydrogen defect. The following quantitative calibration correlates the hydrogen–vacancy complex with the change in Fe²⁺ (equivalent to the net donor concentration)

$$[\text{V}_{\text{In}}\text{H}_4] = 4.2 \times 10^{16} (\text{cm}^{-1}) \times \text{Absorbance} (\text{cm}^{-2}). \quad (7.11)$$

For as-grown InP crystals with net donor concentration less than $4 \times 10^{15} \text{ cm}^{-3}$, the measured absorbance value for the 2316 cm^{-1} feature is slightly less than 0.1 cm^{-2} . This explains why undoped InP crystals are always n-type with *intrinsic* free carrier concentrations of $2\text{--}4 \times 10^{15} \text{ cm}^{-3}$. After annealing, the net donor concentration will be reduced so that it is possible to convert n-type InP with low iron doping to become semi-insulating.

For the case of the rapidly cooled sample, the results are somewhat different. It can be seen from the data in Table 7.3 that the annealing process is somewhat less efficient than for the slowly cooled sample. The change in Fe²⁺ concentration is not as large, indicating that VH₄ donor annihilation is either incomplete or that new compensating acceptors have been introduced during cool-down. Annihilation of VH₄ donors appears to be complete because of the total disappearance of the absorption peak at 2316 cm^{-1} . However, the mechanism of acceptors being quenched in during cool-down remains a possibility. Two observations concerning the quenched sample spectrum in Fig. 7.24 may supply clues to the answer. First, a sharp peak is found at 2204 cm^{-1} . This peak has been identified [7.66] as an LVM belonging to VH₂, an intermediary in the breakup of the VH₄ defect. As the number of H atoms in the vacancy decreases, the P–H bonds lengthen and the frequency of the vibrational mode decreases. As each hydrogen atom is removed from the vacancy, an electron is removed from the highest occupied state. The

Fig. 7.24 A comparison of the absorption peaks in the vicinity of Fe^{2+} intracenter absorption, before and after annealing with rapid cooling

resulting defects, $\text{V}_{\text{In}}\text{H}_2$, $\text{V}_{\text{In}}\text{H}$, and V_{In} , have been identified as single, double, and triple acceptors, respectively, thereby compensating the residual donor concentration. The appearance of the VH_2 defect is likely contributing to the inefficient thermal conversion of quenched InP samples.

Another interesting feature in the IR absorption spectrum of rapidly cooled samples is seen in Fig. 7.24. Before annealing, in the upper plot, two peaks associated with the Fe^{2+} intracenter electronic transition are seen at 2830 and 2844 cm^{-1} . After annealing followed by rapid cooling, the integrated area of the two peaks is reduced, but not as much as for slowly cooled samples, and some new absorption lines emerge at 2864 cm^{-1} and a possible triplet centered around 2877 cm^{-1} . The new peaks are not identified in the literature, and it is not certain if they are caused by electronic transi-

tions or by local vibrational modes. However, because of their similar spacing and proximity to the well-known iron peaks, one could suspect an iron-related defect. Possibly a high-temperature defect becomes quenched in the rapidly cooled samples. For example, if iron diffuses at high temperature by an interstitial mechanism, it is likely that rapid cooling could leave some iron atoms on inactive sites. Substitutional iron (Fe^{3+}) and a low $\text{Fe}^{2+}/\text{Fe}^{3+}$ ratio are required for semi-insulating InP. If iron is trapped on interstitial sites, this will also contribute to the inefficiency of thermal conversion.

Fornari has observed [7.67] that the electrical activity of Fe in as-grown InP is dependent on the annealing cycle which occurs naturally during crystal growth. In other words, the concentration of active iron in a given cross section of the ingot depends on the thermal history and the concentration of In vacancies in that section. This observation led to the development of undoped semi-insulating InP wafers obtained by Fe diffusion [7.68]. In this new approach, unintentionally doped InP crystals were grown and sliced into wafers, which were then annealed at high temperature in an iron phosphide atmosphere. Subsequent electrical characterization showed that the wafers became semi-insulating with resistivities above $10^7 \Omega \text{ cm}$, and mobilities of 3000–4000 $\text{cm}^2/(\text{Vs})$. They also showed that Fe-diffused wafers are more uniform than Fe-doped crystals grown from the melt.

High-temperature annealing of InP has been shown to be an effective way to improve semi-insulating crystal properties. The anneal not only reduces the hydrogen-related donor complexes but also apparently causes Fe redistribution. The concentration of indium vacancies is critical to the annealing process. Substitutional iron requires an indium vacancy in order to be electrically active, just as hydrogen becomes a donor only in the configuration $\text{V}_{\text{In}}\text{H}_4$. With this understanding, it is possible to lower the critical threshold concentration of Fe in semi-insulating InP.

7.6 Optical Characterization of InP:Fe

In order to understand the spatial distribution of iron in InP, a mapping tool that can distinguish between the ionized state Fe^{2+} and the unoccupied Fe^{3+} is needed. Recent advances in optical characterization have developed scanning photocurrent (sPC) as a complement to scanning photoluminescence (PL) measurements [7.69]. Photocurrent mapping experi-

ments are carried out at liquid-nitrogen temperature to improve the contrast [7.70]. The photocurrent is excited by extrinsic light (either $\lambda = 1.32$ or 1.06 μm from a continuous wave (CW) Nd:YAG laser), which implies a probing depth equal to the wafer thickness; on the other hand, PL utilizes above-bandgap excitation wavelength, so the probed depth is on the order of

Fig. 7.25 Scanning PC measurement of InP:Fe with photocurrent intensity as a function of Fe_{In} and the compensation ratio $[\text{Fe}^{3+}]/[\text{Fe}^{2+}]$ (after [7.71])

the minority-carrier diffusion length, or about $1\ \mu\text{m}$. In order to explain the photoconductivity (PC) contrast, a model was developed [7.71] for Fe-doped InP and a direct correlation was found between the PC intensity and the compensation ratio $[\text{Fe}^{3+}]/[\text{Fe}^{2+}]$. This is just the opposite of the PL intensity. It would seem that the contrast in PC images will always be anticorrelated to that of PL images. In fact, the comparison is more subtle, as shown graphically in Figs. 7.25 and 7.26, where the calculated brightness varies with total Fe concen-

tration, considering the compensation ratio as a slope parameter.

Now one can compare the PL and PC images of the same Fe-doped InP wafer to determine if the iron is active or inactive, i.e., substitutional or interstitial. If the two images are anticorrelated as expected, then the compensation ratio will be rather uniform across the wafer. On the other hand, if the both PL and PC images show bright areas at the same location, interesting new possibilities arise. If some areas are correlated and

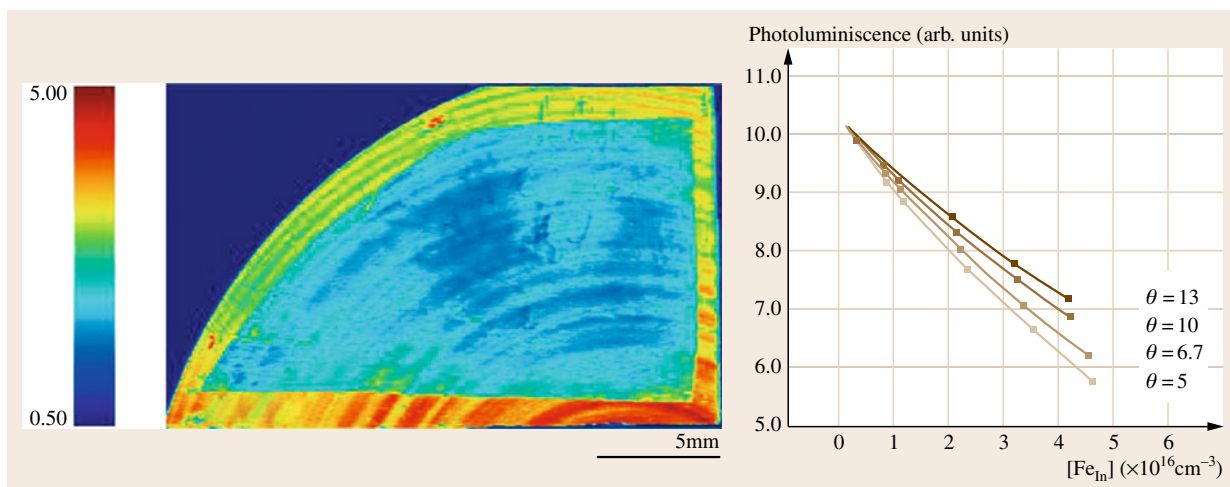

Fig. 7.26 Scanning PC measurement of InP:Fe with photoluminescence intensity as a function of Fe_{In} and the compensation ratio $[\text{Fe}^{3+}]/[\text{Fe}^{2+}]$ (after [7.71])

others anticorrelated, this indicates a nonuniform compensation ratio. Figures 7.25 and 7.26 contain PL and PC images of the same quarter wafer grown for this study of iron distribution. A visual comparison of the two images reveals a bright PC area, which coincides with a bright PL area. This correlated region is a region of low iron concentration but with high compensation. If this is true, it means that the Fe^{2+} concentration must be very low in this region. That means that both the iron atoms and the residual donors are reduced during the crystal growth and cooling process, possibly by a gettering mechanism.

High PL intensity is indicative of low Fe^{3+} concentration. The concentration may be reduced either because the total iron concentration here is low, or because some of the total iron atoms have migrated to inactive sites. On the other hand, high PC intensity indicates a high $[\text{Fe}^{3+}]/[\text{Fe}^{2+}]$ compensation ratio. Since the bright region must contain a low Fe^{3+} concentration, then the ionized Fe^{2+} must be even lower to account for the high PC intensity.

7.7 Summary

The use of applied magnetic fields during liquid-encapsulated crystal growth has been explored as a means to control defect formation in InP crystals. Since magnetic field growth was first suggested as a means to control crystal defects, experimental work has proceeded at several laboratories to understand its effects on melt growth. However, its use has never been adopted for commercial production. The risk may be too high when there is so small a body of knowledge on the subject. This chapter gives a practical review of the advantages and disadvantages of magnetic fields for liquid-encapsulated growth of InP. With the aid of computer modeling, it is possible to design a system with the proper configuration of magnetic field that will optimize the growth properties of InP. Avoidance of twinning, crystal shape control, and control of dopant distribution are goals that should be of interest for commercial production.

This chapter has also contributed to a practical understanding of how dislocations are generated

The PL and PC images present clear evidence that both iron and residual donors are diffusing in the solid during crystal growth. Furthermore, it appears from the annealing experiments that rapid cooling can increase wafer inhomogeneity. Two possible interpretations have been considered. First, the iron may diffuse interstitially, and remain at interstitial sites during rapid cool-down. Second, the iron and residual donors may be precipitating on dislocations by the mechanism of gettering. Either explanation could account for the inhomogeneity seen in the PL and PC images.

In summary, there is no concrete proof that interstitial iron atoms exist at room temperature in InP crystals. However, it can be inferred that the presence of interstitial iron contributes to the inhomogeneity of InP electrical and optical properties. This research has demonstrated that iron atoms as well as residual donors are diffusing rapidly through the crystal and forming precipitates during growth and cooling. Therefore, control over the annealing and cooling cycle is a prime factor in producing semi-insulating InP wafers.

and the mechanism by which they propagate in LEC InP. Dislocations are generated after growth, several millimeters away from the solid-liquid interface. Experiments to control dislocation density by Dash seeding were made possible by magnetic stabilization, but except for small-diameter crystals, the dislocation density is not reduced by magnetic fields, either axial or cusped.

Finally, the activity of iron as a dopant species to control the semi-insulating behavior of InP has been discussed. The simple process of Fe melt-doping is shown to have practical limitations. Control of compensating species and consideration of where the Fe sits in the crystal structure of InP can now be understood in the light of annealing studies. The most uniform crystals may be those that are grown without intentional Fe dopant, and then sliced and annealed to allow iron diffusion after growth. New tools for mapping the charge state of iron in InP have contributed greatly to clarify our understanding of iron activation.

8. Czochralski Silicon Single Crystals for Semiconductor and Solar Cell Applications

Koichi Kakimoto

This chapter reviews growth and characterization of Czochralski silicon single crystals for semiconductor and solar cell applications. Magnetic-field-applied Czochralski growth systems and unidirectional solidification systems are the focus for large-scale integrated (LSI) circuits and solar applications, for which control of melt flow is a key issue to realize high-quality crystals.

Over the past 50 years, single crystals of semiconductors such as silicon (Si), gallium arsenide (GaAs), and indium phosphide (InP) have become increasingly key materials in the fields of computer and information technology. Attempts to produce pure silicon (i.e., a defect-free single crystal of silicon) were motivated by the desire to obtain ultralarge-scale integrated circuits (ULSIs) in which microvoids of about 10 nm diameter [8.1] are formed during crystal growth. Research over the past decade on crystal growth of silicon has focused on analysis of the formation of such microvoids during crystal growth using mass-transfer and reaction equations and on the temperature field in the crystals, obtained from global modeling. Control of solid-liquid interface shapes of GaAs and InP has been extensively studied to find a way to prevent the formation of dislocations and polygonization during crystal growth [8.2–5].

Microvoids are formed by the agglomeration of vacancies introduced at the solid-liquid interface of silicon. In most past studies, it has been difficult to reduce the total number of such microvoids in a whole crystal because the vacancy flux in silicon crystals must be controlled to reduce the probability of agglomeration.

One of the key points for controlling the vacancy flux in crystals, especially that near a solid-liquid interface, is control of the convection of the melt, through which the shape of the solid-liquid interface can be controlled. From this point of view, efforts have been made to control the periodic and/or turbulent flow of melt inside a crucible of large diameter. Crystal growth industries have mainly focused on quantitative prediction of a solid-liquid interface, point defect distribution, oxygen concentration, and dislocation-free growth. Steady (DC) and/or dynamic (AC) [8.6–44] magnetic fields, including electromagnetic fields, are opening up new fields to meet the increasing demand for large-diameter crystals.

A transverse magnetic field (i.e., TMCZ) is the type that has been utilized for commercial production, especially for large-diameter crystals. A lot of research [8.45–49] on the TMCZ method has been published. Numerical calculation [8.50–68] of these transverse magnetic fields is one of the key issues to predict temperature and impurity distributions in the system. Most numerical studies on CZ-Si growth in a transverse magnetic field have been limited to three-

dimensional analysis of melt flow in a crucible by imposing a flat melt–crystal interface and external thermal boundary conditions in the models. However, since the real shape of the melt–crystal interface and the thermal field near it are of great interest commercially, three-dimensional (3-D) global modeling that takes into account the high degree of nonlinearity of the growth system, the inherent three-dimensionality of the melt

flow, and the thermal field under the influence of a transverse magnetic field is necessary. However, there have been few studies using such modeling.

This chapter reviews crystal growth and characterization of CZ silicon. The effects of magnetic fields such as vertical and TMCZ methods on convection of the melt are also discussed. A means for solving the problem of convection computationally is also described.

8.1 Silicon Single Crystals for LSIs and Solar Applications

Figure 8.1 shows the structure of a typical furnace for CZ growth of silicon crystals. The heater, crucible heater, and thermal shields are made of carbon and/or carbon composite. Polycrystalline silicon as a raw material is placed in a quartz crucible. The growth furnace is evacuated, then Ar gas is introduced into the furnace to prevent oxidation of the silicon crystal and the melt. Subsequently, a seed crystal is attached to the top of the melt, then pulled upwards to grow silicon single crystals. The grown crystal is detached from the melt after the end of growth. Finally, the crystal is cooled to room temperature. The diameters of the crystal and crucible are currently 300 and 1200 mm, respectively. The diameter of the crystal is now increasing to 450 mm

in research and development, where the requirement on defect density becomes critical. Therefore, precise control of growth conditions is of great importance to grow defect-free crystals.

8.1.1 Conventional Czochralski Silicon

A seed crystal is usually suspended by a wire, then touches the surface of the silicon melt. The crucible usually rotates to stabilize the flow of the melt through centrifugal forces. The pulling rate of the crystal is also controlled to keep the crystal diameter constant. Monitoring of the diameter is usually carried out by a camera that monitors the meniscus shape. The pulling rate of the crystal is kept at about 1 mm/min, which is important for production efficiency. Oxygen concentration in a crystal is usually controlled by adjusting the pressure and the flow rate of the Ar gas. The crystal and crucible are usually rotated to control impurity and oxygen concentrations as well as the shape of the interface between the crystal and the melt. Moreover, a cone is located near the melt–gas interface to rectify the gas flow just above the melt surface. This cone can control the evaporation rate of oxygen from the top of the melt, which enables control of the concentration of oxygen incorporated from the melt into the crystal.

Bulk crystalline silicon of high quality has become an essential material for today’s information society. The distribution of temperature in a crystal during growth affects the distribution of vacancies and the formation of voids in the crystal. Therefore, it is important to control the temperature distribution in a crystal through control of the flow of the melt. To date, the temperature distribution in the furnace has been controlled by selecting a configuration of the thermal shields based on a global model including heat and mass transfer by radiation, convection, and conduction.

Fig. 8.1 Typical geometry of silicon Czochralski crystal growth furnace

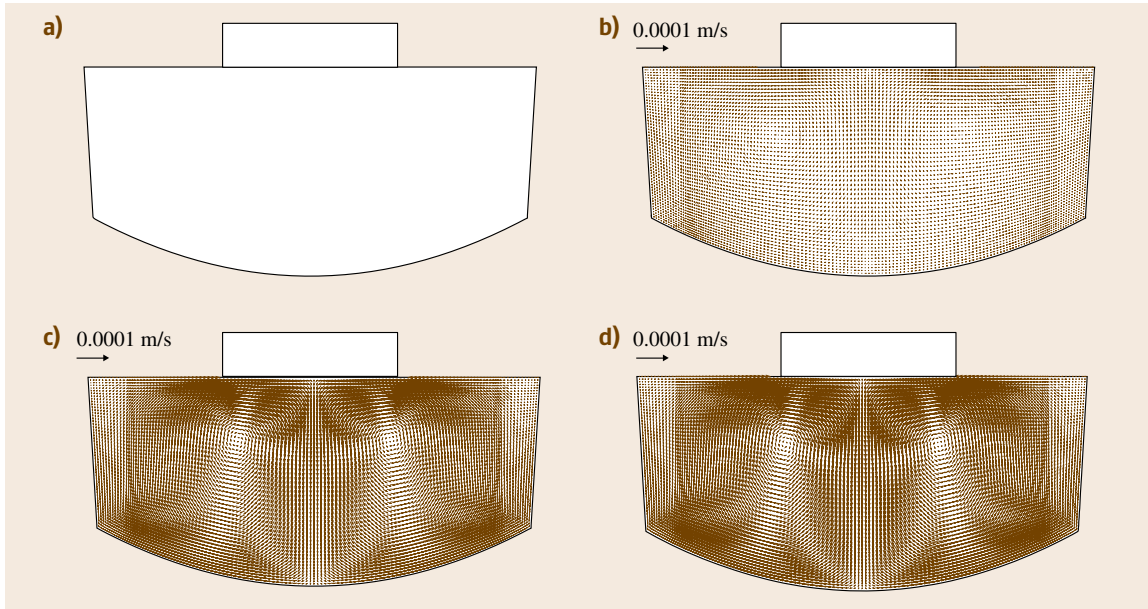

Fig. 8.2a–d Velocity profiles of Czochralski growth of silicon without temperature effect. (a) No forces, (b) with crystal rotation, (c) with crucible rotation, (d) with crystal and crucible rotations

Figure 8.2 shows velocity profiles of Czochralski growth of silicon without the effect of temperature, while Fig. 8.3 shows calculated temperature and velocity profiles of Czochralski growth of silicon including the effect of temperature. These figures clarify how crystal and/or crucible rotation and gravity affect the convection of the melt. This configuration contains melt and a crystal of silicon. Operating conditions in terms of the crystal (ω_s) and crucible (ω_c) rotation rates for Figs. 8.2 and 8.3 are listed in Table 8.1.

Figure 8.2a has no flow since there are no external or internal forces on the melt. Figure 8.2b shows the velocity profile with crystal rotation only, in which case the velocity is low. This is due to the low viscosity of the silicon melt, which cannot diffuse momentum effectively from the crystal to the melt. Figure 8.2c,d shows similar profiles with the crucible rotating, showing the large effect of crucible rotation on convection of the melt.

Figure 8.3 shows the temperature profiles under the conditions listed in Table 8.1. Figure 8.3a and b show almost the same profiles of temperature and velocity, similar to the relationship between Fig. 8.2a,b. This is because of the low viscosity of the melt.

Figure 8.3c,d shows a low velocity and a temperature profile similar to that for the conduction-dominated

case. This small velocity is attributed to the law of conservation of angular momentum in the rotating melt [8.26]. The momentum (Navier–Stokes) equation for the rotating melt contains terms for the Coriolis and centrifugal forces, as shown in (8.1), for the rotating coordinate system

$$\frac{\partial \mathbf{u}}{\partial t} = -\mathbf{u} \nabla \mathbf{u} - 2(\Omega \mathbf{k}) \times \mathbf{u} + (\Omega \mathbf{k}) \times (\Omega \mathbf{k}) \times \mathbf{r} + \frac{1}{\rho} \nabla p + \mu / \rho \Delta \mathbf{u} + \mathbf{g} \beta (T - T_0), \quad (8.1)$$

where \mathbf{u} and \mathbf{r} are the vectors of relative velocity on a rotational basis and position, respectively, Ω denotes the crucible rotation rate, p and μ represent the pressure and viscosity of the melt, and \mathbf{g} , β , and T_0 are the vectors of gravitational acceleration, the volume expansion coefficient, and the reference temperature

Table 8.1 Operating conditions of crystal (ω_s) and crucible (ω_c) rotation rates

ω_s	0	−3	0	−3
ω_c	0	0	10	10
Figure 8.3	a	b	c	d
ω_s	0	−3	0	−3
ω_c	0	0	10	10

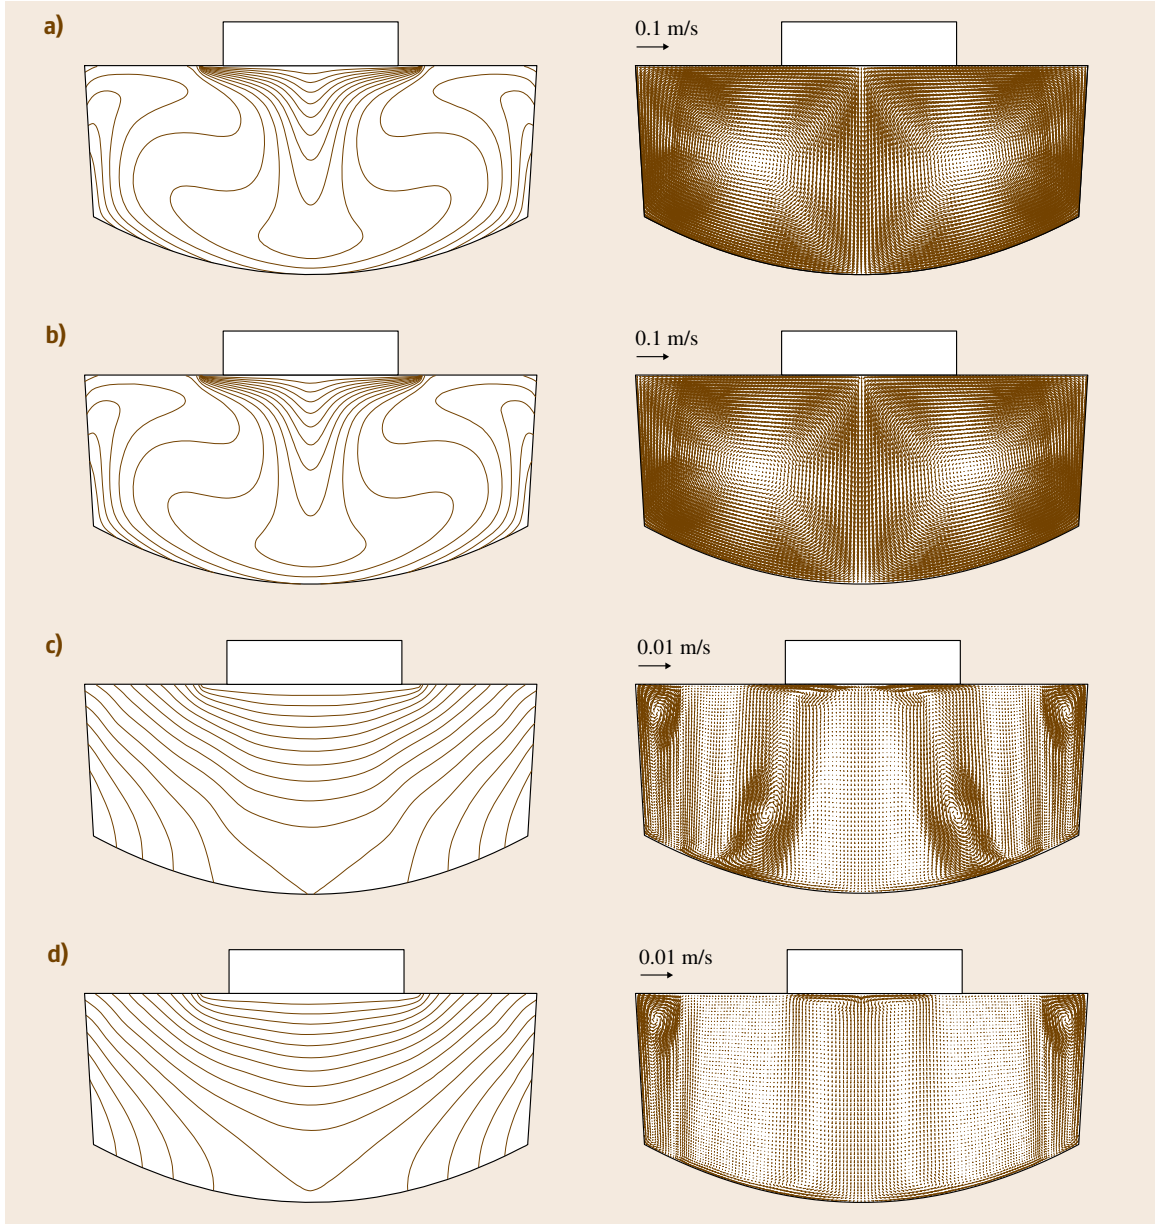

Fig. 8.3a–d Temperature and velocity profiles of Czochralski growth of silicon without temperature effect. **(a)** No forces, **(b)** with crystal rotation, **(c)** with crucible rotation, **(d)** with crystal and crucible rotations. Temperature difference between the contours is $\Delta T = 5$ K. Consequently, the centrifugal force always acts in the opposite direction. This means that the melt motion in the radial direction is suppressed by the crucible rotation

corresponding to specific mass, and the reference temperature of 1685 K, respectively. The second and third terms on the right-hand side of (8.1) express the Corio-

lis force and centrifugal acceleration, respectively. The vector \mathbf{k} in (8.1) is a unit vector in the z -direction. The centrifugal acceleration vector (\mathbf{a}_{cen}) can be expressed

as (8.2).

$$a_{\text{cen}} = \Omega^2 r = \frac{L^2}{r^3}, \quad (8.2)$$

where L is the angular momentum of the melt.

When a small volume element moves instantaneously from position r to $r' (= r + \Delta r)$, the excess force shown in (8.3) is caused by the conservation of angular momentum

$$\Delta a_{\text{cen}} = L^2 \left(\frac{1}{r^3} - \frac{1}{r'^3} \right). \quad (8.3)$$

8.1.2 Magnetic Czochralski (MCZ) Silicon

As the diameter of the crystal increases we need to stabilize the flow of the melt. There have been a lot of papers regarding the magnetic-field-applied Czochralski method, especially for large-diameter crystals [8.35–45]. Research on electromagnetic hydrodynamics has a long history in the field of steel and metal manufacturing processes. Since molten silicon, like molten steel or metal, has many free electrons, electromagnetic hydrodynamics can be used to control the convection in metalically conducting molten silicon through the application of magnetic and/or electric fields.

The electric current (\mathbf{J}) in the melt and the Lorentz force (\mathbf{F}) induced by the current in the case of a steady electromagnetic field are shown in (8.4) and (8.5), respectively, where σ_e , \mathbf{E} , \mathbf{B} , and \mathbf{v} are the electric conductivity of the melt, electric field, magnetic flux density, and velocity of the melt, respectively.

$$\mathbf{J} = \sigma_e (\mathbf{E} + \mathbf{v} \times \mathbf{B}), \quad (8.4)$$

$$\mathbf{F} = \mathbf{J} \times \mathbf{B}. \quad (8.5)$$

Due to the continuity condition on the electric current in the melt, (8.6) (a Poisson-type equation) should be satisfied, since there is no source of charge in this case:

$$\nabla \cdot \mathbf{J} = 0. \quad (8.6)$$

The typical magnetic fields used in the Czochralski method are shown in Fig. 8.4. Figure 8.4a and b show schematic diagrams of the vertical magnetic-field-applied Czochralski (VMCZ) and the transverse magnetic-field-applied Czochralski (TMCZ) method, respectively. One or two coils are set parallel to the pulling axis in VMCZ, while two coils are set perpendicular to the axis in TMCZ. For the cusp-shaped magnetic-field-applied Czochralski method there are two coils, which are set parallel to the axis with opposite current directions. Therefore, inhomogeneous magnetic fields are applied to the melt.

Fig. 8.4a,b Schematic diagram of a VMCZ (a) and TMCZ (b) system. Static current is applied to the cylindrical coil. Schematic diagram of electric currents and Lorentz forces under vertical magnetic fields

The vertical magnetic-field-applied Czochralski (VMCZ) method was one of the methods used in early works on magnetic-field-applied crystal growth. Magnetic fields are applied in the z -direction; therefore, motion of the melt in the radial and/or azimuthal directions reacts with the magnetic field, while melt motion in the vertical direction does not react with the field. Electric current is induced in the azimuthal direction by the radial motion of the melt under a vertical magnetic field. Therefore, the Lorentz force works in the opposite direction and suppresses the velocity of the melt in the radial direction.

Fig. 8.5 Relationship between magnetic field and flow velocity in a meridional plane under vertical magnetic fields (after [8.35, 50])

Radial current, which is induced by a coupling with the azimuthal velocity and magnetic field, cannot flow through the crucible wall as it is electrically insulating. Thus, the Lorentz force cannot work, and the melt flows freely in the azimuthal direction.

Figure 8.5 shows experimental results for the melt velocity in a meridional plane obtained by a visualization technique using an x-ray radiography method [8.52]. The dots show experimental data while the lines show results of numerical calculation using a three-dimensional configuration of the melt. This figure clearly shows that there is a reduction in melt motion in the meridional plane. It was clarified from the visu-

alization that the motion in the azimuthal direction was not suppressed.

The TMCZ system has a nonaxisymmetric configuration, and temperature and velocity fields therefore have twofold symmetry. Although this system has such a symmetry, it has been used for actual production of silicon for charge-coupled devices (CCDs), since the system enables crystals with low oxygen concentration to be produced. CCDs should have homogeneous and low oxygen concentration for reduction of inhomogeneity of image cells in the devices.

An elliptic temperature distribution due to inhomogeneous heat transfer in the melt can be seen in

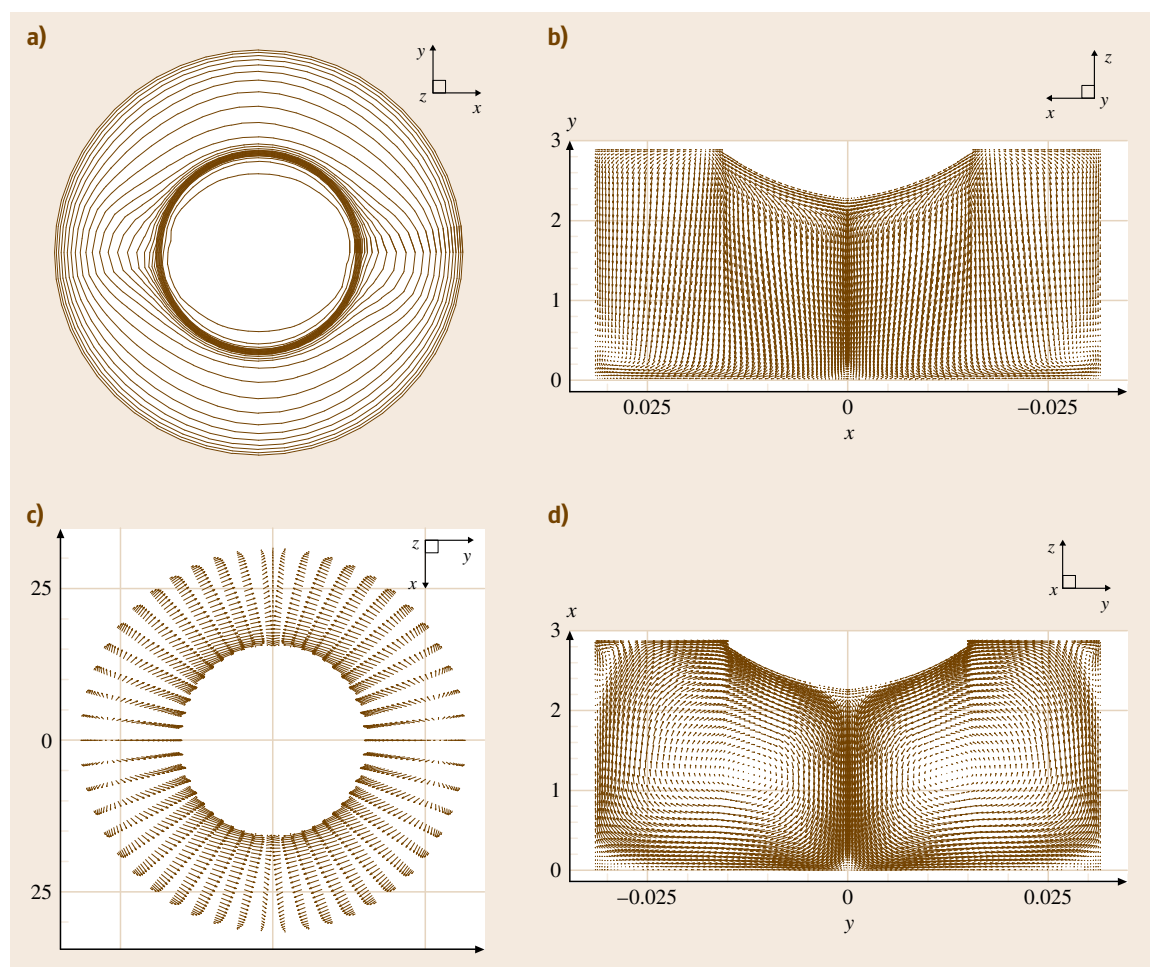

Fig. 8.6a–d Temperature and velocity distribution in silicon melt with a transverse magnetic field applied in the x -direction. Distributions of temperature (a) and velocity (c) at the top of the melt. Velocity distributions in planes perpendicular (b) and parallel (d) to the magnetic field. Temperature difference between the contours is 2 K. Average velocities of (b), (c) and (d) are 0.2, 0.18 and 0.19 mm/s, respectively

Fig. 8.6a. As shown schematically in Figure 8.6a,b, only down-flow is formed in a plane parallel to the magnetic field, while two roll cells are formed in a plane perpendicular to the field. Consequently, thin boundary layers of velocity, temperature, and oxygen near the crucible wall are formed.

This phenomenon is a characteristic of a transverse magnetic field, which is static and nonaxisymmetric. If an axisymmetric magnetic field such as a vertical or cusp-shaped field is used, the melt rotates with the same angular velocity as the crucible.

8.2 Control of Crystal Defects in Czochralski Silicon

Microvoids are formed by agglomeration of vacancies that are introduced at a solid–liquid interface of silicon [8.1, 51–55]. In most past studies, it has been difficult to reduce the total number of such microvoids in a whole crystal because the vacancy flux in silicon crystals must be controlled to reduce the probability of agglomeration.

One of the key points for controlling the vacancy flux in crystals, especially that near a solid–liquid interface, is control of the convection of melt, by which the shape of the solid–liquid interface can be controlled. From this point of view, efforts have been made to control the periodic and/or turbulent flow of melt inside a crucible of large diameter. Crystal growth industries have mainly focused on quantitative prediction of a solid–liquid interface, point defect distribution, oxygen concentration, and dislocation-free growth.

8.2.1 Criterion for Characteristic Defect Formation

Point defects such as a vacancy and an interstitial atom form clusters which become microvoids and dislocation clusters. Such defects degrade characteristics of LSIs by formation of leakage current paths. The microvoids and dislocation clusters are formed by supersaturation of vacancy and interstitial atoms during the crystal cooling, respectively. If the total number of vacancy and interstitial atoms is the same, they can compensate, and perfect crystal will then be formed. However, such condition cannot be realized due to differences in their equilibrium concentrations at melting point and their diffusion constants. The interstitial atoms migrate fast near the melting point while vacancies move with the pulling speed since their diffusion constant is small.

Fig. 8.7 (a) Temperature distribution in a global model with a two-dimensional configuration. (b) A zoomed temperature distribution in a global model with a two-dimensional configuration. Temperature difference between the contours is 5 K

Volonkov proposed (8.7) as the criterion to obtain perfect crystals [8.52]

$$\frac{V}{G} = 0.62, \quad (8.7)$$

where V and G are the crystal pulling rate and the temperature gradient of the crystal, respectively.

The flux of vacancy transfer in a crystal is determined by the crystal pulling speed since vacancies, with a slow diffusion constant, move with the pulled crystals. However, the flux of interstitial atoms in a crystal is determined by the temperature gradient of the crystal since interstitial atoms diffuse based on the gradient of the equilibrium concentration. Such concentration gradients are defined by the temperature gradient in a crystal. Therefore, the dominant defect can be determined by the relationship expressed by (8.7).

To obtain a perfect crystal one has to control the flux of defects in a crystal. We need to control these fluxes by controlling the temperature distribution in the furnace and the shape of the solid–liquid interface, which affects the temperature gradient in the crystal. We usually use a global model that can predict the temperature distribution in a furnace, including the shape of the solid–liquid interface. The global model contains conduction, convection, and radiation of heat and mass transfer in the furnace.

Figure 8.7a,b [8.55] shows two-dimensional temperature distributions in a furnace at Kyushu University. We can recognize temperature distributions in each part of the crystal, crucible, melt, heater, and thermal shields. If the system is completely axisymmetric, a two-dimensional configuration can be imposed due to the almost axisymmetric configuration of a Czochralski furnace. However, many studies have shown that flow in the melt has a three-dimensional structure. Therefore, we have to change the configuration from two to three dimensional.

8.2.2 Effect of Pulling Rate and Temperature Gradient

We usually use magnetic fields to control temperature gradient in a crystal through control of the flow of the melt. The results of a series of computations with various intensities of magnetic field and various crystal pulling rates are summarized in Figs. 8.8 and 8.9. Figure 8.8 shows the axial temperature gradients in both the crystal and the melt at a melt–crystal interface as a function of crystal pulling rate. Solid lines show the results with and without a magnetic field, while dashed lines

Fig. 8.8 Axial temperature gradients in the crystal (*upper part*) and melt (*lower part*) near the interface as a function of pulling rate of a crystal at different intensities of the applied magnetic field (after [8.55])

show the results without convection in the melt, approximately corresponding to the case with a magnetic field intensity of infinite value. The arrows in the figure show the contribution of the convection of the melt. The val-

Fig. 8.9 Interface deflection as a function of pulling rate of a crystal at different intensities of the applied magnetic field (after [8.55])

ues of the axial temperature gradients in the melt and crystal were obtained by averaging in the central area of the interface. The values of the axial temperature gradients in the melt and crystal at the interface are not identical even when the crystal pulling rate is zero since the thermal conductivity of the crystal is not equal to that of the melt.

These results show that the axial temperature gradients in the melt and crystal near the interface increase with increasing magnetic field intensity. With increasing crystal pulling rate, the temperature gradient near the interface in the crystal increases, while that in the melt decreases. Meanwhile, the difference between the case with finite (including zero) magnetic field intensity and the case without melt convection becomes smaller. Since this difference is due to the melt convection, this result indicates that the contribution of melt flow becomes smaller with increasing crystal pulling rate.

These phenomena can be explained as follows. When we apply a magnetic field of large intensity natural convection of the melt is suppressed, resulting in a more inhomogeneous temperature distribution in the melt. Therefore, the temperature gradient in the melt increases with increasing magnetic field intensity. Meanwhile, because of heat balance between the liquid and solid at the interface, the temperature gradient in the crystal near the interface also increases accordingly. However, melt convection still remains, even if we apply a magnetic field with a relatively large intensity to the melt. As a result, even when a relatively large magnetic field of 0.3 T is applied to the system, the temperature gradients near the interface in both the crystal and the melt are far from those without melt convection, as shown in Fig. 8.8. On the other hand, since a larger crystal growth rate always results in lower heater power, the temperature on the sidewall of the melt becomes smaller due to the lower heater power. The temperature

difference becomes smaller and the temperature distribution becomes less inhomogeneous in the melt. This in turn leads to weaker melt convection due to decrease in the thermal buoyancy force induced by the temperature gradient in the melt. Therefore, with increase in the crystal pulling rate, both the axial temperature gradient in the melt near the interface and the contribution of melt convection decrease. However, since the heat released due to solidification at the interface is proportional to the crystal growth rate and it is transported away from the interface through the crystal, a larger axial temperature gradient field is generated in the crystal near the interface when the crystal pulling rate is increased.

Figure 8.9 shows the interface deflection toward the melt as a function of the ratio between the crystal pulling rate (V_p) and the temperature gradient in the crystal near the interface (G). The values of the interface deflection and the parameter V_p/G were obtained by averaging in the central area of the interface. The arrows in the figure show the contribution of convection in the melt. The interface moves upward to the crystal side with increase in either the magnetic field intensity or the value of the parameter V_p/G . This tendency is consistent with that of the axial temperature gradient in the crystal near an interface shown in Fig. 8.8. This is because the interface shape is mainly determined by the temperature distribution in the crystal close to the interface and the melt convection in the crucible. As explained in the previous section, when a magnetic field of large intensity is applied to the system or a larger pulling rate is applied to the crystal, the melt convection is suppressed and the axial temperature gradient in the crystal near the interface increases. The melt–crystal interface then moves upward to the crystal side in order to accommodate the increased axial temperature gradient in the crystal near the interface and the contribution of melt convection in the crucible becomes smaller.

8.3 Growth and Characterization of Silicon Multicrystal for Solar Cell Applications

Casting is a key method for large-scale production of multicrystalline silicon for use in highly efficient solar cells [8.56, 69–71]. Since the efficiency of solar cells depends on the quality of the multicrystalline silicon, which is in turn determined by the crystallization process, it is important to investigate and optimize the

casting process to control the distributions of temperature and iron in a silicon ingot during the solidification process. Moreover, dislocation plays an important role in the efficiency of solar cells. Such properties should be controlled carefully by using a large-scale calculation in order to obtain silicon crystals for solar cells.

Fig. 8.10 Configuration and computation grid of a casting furnace. The melt, a crystal, a crucible, a crucible holder and pedestals are denoted as 1, 2, 3, 4, 5, and 6, respectively. Thermal shields are labeled 7–11. The numbers 12 and 13 indicate multiple heater

8.3.1 Recent Development of Crystalline Silicon for Solar Cells

Numerical simulation has become a powerful tool for investigation and optimization of the casting process and crystal growth process with the development of computer technology and computational techniques [8.56, 57]. Since a casting furnace has a highly nonlinear conjugated thermal system, transient simulation with global modeling is an essential tool for investigation and improvement of the casting process. We developed a transient code with a global model for the casting process and carried out calculations to investigate the distributions of temperature and iron in a silicon ingot during the casting process.

8.4 Summary

Crystal growth and characterization of Czochralski silicon single crystals for semiconductor and solar cell application is a key technology for information and renewable energy. Such activity enables us to open up

Fig. 8.11 Distribution of iron concentration in a solidified silicon ingot after the solidification process. The scale of iron concentration should be multiplied by $1 \times 10^{10} \text{ cm}^{-3}$. The periphery of the crystal contains on the order of $1 \times 10^{15} \text{ cm}^{-3}$

Time-dependent distributions of iron and temperature in a silicon ingot were investigated. Figure 8.10 shows a typical casting furnace for production of multicrystalline silicon for solar cells.

Figure 8.11 shows the distribution of iron concentration in a solidified silicon ingot that had been cooled for 1 h during the cooling process. The figure shows a vertical cross-section of the iron concentration in the crystal. The scale of the iron concentration should be multiplied by $1 \times 10^{10} \text{ cm}^{-3}$; therefore, the periphery of the crystal contains on the order of $1 \times 10^{15} \text{ cm}^{-3}$.

Areas with high iron concentration were formed at the top of the melt due to segregation of iron. Moreover, areas with high concentration of iron were formed close to the crucible walls. Such areas were formed by diffusion, which occurred during solidification and the cooling process. This is based on the small activation energy of iron diffusion in solid silicon. The central area of the ingot has a low concentration of iron after the solidification process, as shown in Fig. 8.11.

a new world through technological breakthroughs. Both experimental and numerical studies on crystal growth help us to understand and derive new concepts for new crystal growth technology.

Czochralski Growth of Oxide Photorefractive Crystals

Ernesto Diéguez, Jose Luis Plaza, Mohan D. Aggarwal, Ashok K. Batra

Czochralski crystal growth is one of the major methods of crystal growth from melt for bulk single crystals for commercial and technological applications. Most crystals, such as semiconductors and oxides, are grown from melt using this technique due to the much faster growth rates achievable. A detailed description of the process can only be given for specific materials; there is no universal crystal pulling system available commercially. The details of the basic principle and the design of automatic diameter control Czochralski crystal growth system elements are given in this chapter so as to enable any researcher to design and fabricate his/her own system. This chapter is devoted to the growth of bulk oxide photorefractive materials such as lithium niobate and sillenite crystals including the development in these materials during the last decade. A number of problems (and possible solutions) encountered by the authors during growth in their respective laboratories over the last two decades are discussed.

Section 9.2 provides the introduction to crystals and crystal growth mechanism and various methods of growing photorefractive crystals. Section 9.3 discusses in detail the Czochralski method of crystal growth, including selection of appropriate components for setting up a crystal growth system such as the heating system design, and raising, lowering, and rotation mechanisms. Section 9.4 discusses the growth and properties of lithium niobate crystals. A brief introduction to other photorefractive crystals is given in Sect. 9.5. The details of the growth and properties of sillenite crystals are given in Sect. 9.6. Section 9.7 summarizes the present state of these two important crystals in terms of growth and applications.

9.1 Background

With the rapid growth of the electronic and optoelectronic industries, the demand for crystalline materials has increased dramatically over the past few decades. The requirement for better, cheaper, and larger single crystals has driven extensive research and development in crystal growth. A major factor behind such growth is the advent of high-power and efficient solid-state lasers, in combination with the use of materials that exhibit large second- or third-order nonlinearities [9.1–3]. In such conditions, nonlinear optics is becoming an important technology in the design of new laser sources emitting in the visible or near infrared. Nonlinear optics also enables the attainment of new functionalities in laser systems and in optoelectronic signal transmission and processing. The class of nonlinear phenomena based on the photorefractive effects in electrooptic crystals will undoubtedly play a major role in these various applications of laser photonics. Since its discovery, photorefraction has stimulated much basic research, covering both fundamental materials studies and their applications in dynamic holography, laser beam control, and optical processing. For many years the challenge was only to understand the basic mechanisms of photorefraction giving rise to this effect in different crystals, which drove research and development in this area. More and more materials were found to be photorefractive. New electrooptic interactions were discovered. The fields of nonlinear optics, optical spectroscopy, electrooptics, ferroelectrics, electronic transport, and Fourier optics were brought together to develop a complete

understanding of the complex microscopic mechanism involved. Another important aspect of photorefractive materials is their ability to perform efficient energy transfer between a signal and a reference beam interfering in the volume of the crystal. This property opens up a wide range of applications, including image amplification, optical phase conjugation with gain, and self-pumped optical cavities. To achieve these results and develop applications requires us to optimize nonlinear material properties, and therefore the choice of the best material is a critical issue. Nonlinear photorefractive optics is now well established and has reached scientific maturity. It contributes to stimulate basic research in solid-state physics and to investigate in detail the mechanisms of charge transport in different types of ferroelectric or semiconductor crystals such as LiNbO_3 , BaTiO_3 , KNbO_3 , $\text{Bi}_{12}\text{SiO}_{20}$ or GaAs.

The Czochralski method is most popular and useful for the growth of large oxides crystals. This chapter is devoted to the growth of bulk photorefractive materials from the Czochralski method, summarizing the development in these materials during the last decade. We focus our attention on the two most important photorefractive materials, LiNbO_3 and sillenites, which are considered the most relevant, especially because in these two materials all the problems and circumstances inherent to bulk crystal growth of photorefractive oxide materials are concentrated. For this reason the chapter includes various sections devoted to each of these materials.

9.2 Crystal Growth

9.2.1 Czochralski Method of Crystal Growth

The CZ technique is named after J. Czochralski. Czochralski's invention was discovered essentially by accident. As the story goes, the young Czochralski, then chief of AEG's metal laboratory in Berlin, was studying the crystallization of metals. A crucible containing molten tin was left on his table for slow cooling and crystallization. Czochralski was preparing his notes on the experiments carried out during the day when at some point, lost in thought, he dipped his pen into this crucible instead of the inkwell placed near the crucible. He withdrew it quickly and saw a thin thread of so-

lidified metal hanging at the tip of the nib. Thus, the discovery was made. He had discovered a phenomenon never observed before: crystallization by pulling from the surface of a melt. However, careful observation of this accidental process provided a discovery of great importance. Later, the nib slot, in which crystallization was initiated, was replaced by a special narrow capillary and later by a seed crystal of the material to be grown [9.4]. *Teal* and *Little* also grew germanium single crystals by similar technique [9.5]. In the recent past, *Brandle* has given a detailed description of Czochralski growth of oxides along with current status [9.6].

Fig. 9.1 A basic diagram of the Czochralski method ►

A basic diagram of the CZ method is illustrated in Fig. 9.1 with various components to explain the process. To be considered as a possible candidate for crystal growth by the Czochralski technique, the material should have a relatively low vapor pressure. The crucible material should be nonreactive with the crystal growth material above its melting point. The Czochralski system is based on the following principle: the material is melted in a crucible and is kept for a certain time at a temperature above the melting point, then the temperature is reduced to a value slightly above the freezing point. The freezing point is judged by cooling the melt until crystals start to appear on the surface, then the temperature is slightly lowered and a seed (cut in the appropriate orientation) is inserted into the melt. It is kept at that position for a little while, then the pulling mechanism is started. The seed forms a crystallization center if the temperatures have been chosen correctly. If the crystal starts growing very fast and becomes visible to the naked eye, then the temperature of the melt needs to be increased by a degree or so; the melt must not be overheated as this would cause the crystal to dissolve and separate from the melt. The diameter of the pulled crystal is controlled by manipulating the temperature of the melt and the pulling rate. Suitable engineering of both axial and radial temperature gradients

is needed to grow single crystals of desired dimensions reliably.

9.3 Design and Development of Czochralski Growth System

In this section, various components and instruments used for developing the automatic diameter control CZ technique are discussed so that the reader can set up his/her own system. The major components are: furnace design, heating methods viz. resistive or inductive, temperature control techniques, crucible selection, and crystal rotation and pulling arrangement [9.7].

9.3.1 Furnace Construction

The furnace used for crystal pulling can vary from the very simple, e.g., a resistance wound heating element, to one which is extremely complex because of thermal and chemical constraints placed upon it by the crystal. Two types of furnaces can be used; the first type is for oxide crystal growth and is generally composed of ceramic and noble-metal parts, whereas the second type is for semiconductor growth and is usually composed

of graphite and fused-silica parts. For growing lithium niobate crystals, a resistance or inductive furnace can be utilized.

9.3.2 Heating Methods

Selection of the heating method depends on the operational temperature needed to grow single crystals of the desired material. This normally depends on the melting temperature, which can be determined from the phase diagram, which is essentially a first road map for the crystal grower. The basis for selection of the heating method is also determined by the following factors: the method of heat transfer (radiation, conduction or convection), the rate of heating or thermal transfer, the degree of uniformity of the temperatures, the shape of the temperature gradients, the precision needed in controlling the temperature, the furnace atmosphere, and

Table 9.1 Some useful properties of common resistance and heating elements

Material and trade name	Maximum operating temperature (°C)	Permissible atmosphere
Kanthal	1250	Oxidizing or reducing

Tungsten	3000	Inert or vacuum
Nichrome	1200	Oxidizing or reducing
Platinum	1450	Oxidizing or reducing

the cost of the heating equipment. The variety of heating methods for crystal growth may be categorized mainly in two categories, viz. resistance heating or induction heating. Some useful properties of common resistance heating element materials are listed in Table 9.1. As can be seen, resistance-heated furnaces are normally limited to lower temperature ranges (up to 1600 °C) and can have one of the several types of elements listed in the table. A general advantage of resistance-heated furnaces over other types is their greater electrical efficiency and reduced operational costs.

High-frequency heating is of major importance in crystal growth because a large range of temperatures can be achieved with a reasonably high efficiency of energy transfer and it can be used in a variety of processes. Radiofrequency (RF) induction heating provides the cleanest and most readily available method of heating precious-metal crucibles, although in the interest of economy, resistance heating is sometimes used, especially for lower-melting-point materials. Induction heating normally occurs in a conducting material due to eddy currents induced in the conductor by the electromagnetic field from a high-frequency current-carrying coil (the RF work coil) that surrounds the charge. The useful RF band is typically 100 kHz to 10 MHz, although for relatively large metallic ingots, frequencies in the medium frequency band (0.5–10 kHz) are useful and advantageous. In fact, most of the heat is generated in the skin layer over the coupled flux volume of the conductor. If a nonconducting crucible is required, a graphite susceptor should be utilized, which is heated first and then conducts heat to the charge in the crucible.

This source of heating is generally used for higher-melting oxides such as sapphire (Al₂O₃) and garnets;

however, it can be used for the growth of semiconductor materials. Usually RF generators operate in the above-mentioned frequency range and with a wide power range of 10–100 kW. For general laboratory use, a 10–30 kW RF generator is suitable and provides the capability to grow crystals up to about 30–50 mm in diameter.

9.3.3 Temperature Control Techniques

Thermocouples are routinely used for measuring the temperatures in these systems. There are a large number of thermocouple available including Chromel/Alumel, Pt-Pt10%Rh, and Pt-Pt13%Rh. Junctions between two thermocouples metals are produced by either fusing the two wires in a gas flame or by spot welding. Mechanical and brazed connections can also be used. Nowadays cold junction compensation is available for all types of thermocouples in any temperature measuring thermocouple thermometer. Basically these provide a zero suppression in accordance with the electromotive force (EMF) generated by the cold junction. Some of the most commonly used thermocouples are listed in Table 9.2.

Most conventional temperature controllers, whether analog or microprocessor based, are three-mode proportional–integral–differential (PID) controllers. This means that the control algorithm is based on a proportional gain, an integral action, and a derivative action. The proportional band simply amplifies the error between the set point and the measured value to establish a power level. The term *proportional band* (PB) expresses the gain of the controller as a percentage of the span of the instrument. A 25% PB equates to a gain of 4, whereas a 10% PB corresponds to a gain of 10. Given the case of a controller with a span of 1000 degrees, a PB of 10% defines a control range of 100 degrees around the set point. If the measured value is 25 degrees below the set point, the output level will be 25% heat. The proportional band determines the magnitude of the

Table 9.2 Most commonly used temperature sensors

Type and trade name	Thermocouple/sensor elements	Range (°C)
K	Chromel/Alumel	0–999
J	Iron/Constantan	0–500
R	Pt /13%Rh-Pt	0–1760
S	Pt /10%Rh-Pt	17–1760
B	Pt / 6% Rh-Pt /30%Rh	24–1820
C	W/5%Re-W/26%Re	17–2320
Spot pyrometer	Optical pyrometer	600–3000

response to an error. If the proportional band is too small, meaning high gain, the system oscillates and is overresponsive. A wide proportional band, i.e., low gain, could lead to control *wander* due to a lack of responsiveness. The ideal situation is achieved when the proportional band is as narrow as possible without causing oscillation.

Integral action, or automatic reset, is probably the most important factor governing control at a set point. The integral term slowly shifts the output level as a result of an error between the set point and the measured value. If the measured value is below the set point the integral action will gradually increase the output power level in an attempt to correct this error. Expressed as a time constant, the longer the integral time constant, the more slowly the power level will be shifted (the fewer repeats/min, the slower the response). If the integral term is set to a fast value the power level will be shifted too quickly, thus causing oscillation since the controller is trying to work faster than the load can change. Conversely, an integral time constant which is too long will result in very sluggish control. The derivative action or rate provides a sudden change in output power level as a result of a quick change in measured value. If the measured value drops quickly the derivative term will provide a large change in output level in an attempt to correct the perturbation before it goes too far. Derivative action is probably the most misunderstood of the three. It is also most beneficial in recovering from small perturbations.

An optical pyrometer is another well-accepted noncontact temperature measuring device. Optical pyrometers work for temperatures up to 3000 °C.

9.3.4 Common Crucible Materials

The chemical and physical stability of the crucible in the processing environment are important factors that dictate the selection of the material used to fabricate

it. The design and choice of the material for the crucible are critical. The crucible should not contaminate or stress the crystal. If possible it should have a thermal conductivity similar to that of the charge to ensure that planar isotherm profiles exist in the vicinity of the melting point of the charge, thus ensuring that the crystallizing interface is near planar. For crystal growth of metals, quartz and graphite are most often used. Some of the common materials used to make crucibles are listed in Table 9.3.

9.3.5 Crystal Rotation and Pulling Arrangement

A schematic of the crystal pulling arrangement used in author's laboratory is presented in Fig. 9.2. In this arrangement, circular motion of the motor is converted to linear motion by using a lead screw with a specific pitch. A rotation motor is attached to the cantilever arm. A load cell measures the weight of the growing crystal and also holds the seed rod. A gearbox arrangement is used to adjust the pulling rate, and the rotation rate is adjusted separately using a stepper motor and its controller.

9.3.6 The Czochralski Crystal Growth System

Using the above-described components, automatic diameter control for a CZ system has been designed and fabricated [9.8, 9]. The system consists of an electrical furnace with global heat elements that generates the required temperature gradient, seed rotation and lowering mechanisms, and an Hottinger Baldwin Messtechnik GmbH (HBM) electronic balance/load cell which can measure the weight of a growing crystal to the nearest 0.1 g. The temperature of the furnace goes up to 1500 °C, controlled using a Eurotherm 818 temperature controller. The data for the control thermocouple and from the balance are monitored by a personal computer, which through a central program, written in Visual Basic 6.0/BASIC (described below), sets the temperature controller to the required temperature set point. Two different stepper motors interfaced to a personal computer control the pulling and rotation of seed crystals. A photograph of the CZ crystal growth system used in the authors' laboratory using an induction heating system is shown in Fig. 9.3. Figure 9.4 shows a block diagram of the complete setup of the same Czochralski crystal growth system. An isometric view of a Czochralski crystal puller used in the laboratory at Alabama A&M University is shown in Fig. 9.5.

9.3.7 Automatic Diameter Control for Czochralski Crystal Growth Technique

In order to reproducibly grow high-quality single crystals the best control techniques need to be considered. In this subsection we will discuss the use of automatic diameter control systems for Czochralski crystal growth from melt [9.9, 10]. Various techniques for automatic diameter control are available, including optical methods (i.e., analysis of a video or x-ray image of the growing crystal) as well as weight monitoring, which consists of weighing the crystal and seed holder, as used in the authors' laboratory in the present system, or by weighing the crucible and its contents. The relative merits of some of these systems are reviewed in the literature [9.7]. Briefly, optical methods depend on the availability of a clear optical path to view the growth interface, which may be difficult to maintain over the time required for growth. Weighing the crucible gives a poorer ratio of signal (weight change per unit time) to total weight than weighing only the crystal and seed holder. In addition, if induction heating is used, the radiofrequency (RF) field exerts a vertical force on the crucible (proportional to the instantaneous power) which must be taken into account to obtain accurate weight change data. To control the crystal growth process and achieve/maintain a specific crystal diameter, a program in Visual Basic 6.0 was designed and developed. The Visual Basic program has near-real-time access to all data, control characteristics, and user-friendly interfaces for user interaction with the software and access to archival data. The algorithm, written in Visual Basic, provides control of the complete crystal profile during seed extension and growth of the crystal to the desired diameter, termination of the growth process, and cooling of the grown crystal to room temperature. The slope of crystal weight over time is used to compute the diameter of crystal. All the parameters required for growth runs need to be optimized for each material, and the desired sizes of crystal are stored in a parameters file. The parameters stored in the file are crystal density, melt density, crucible diameter, seed length, seed diameter, cone angle crystal diameter and growth rate, control loop parameters including proportional–integral–derivative (PID) values for different stages of growth, fitting factors for minimizing noise during data acquisition, and feedback values. The controlled parameter is the power to the furnace through the Eurotherm 818 process controller. In the current application, the weight reading is taken at 6 s intervals but

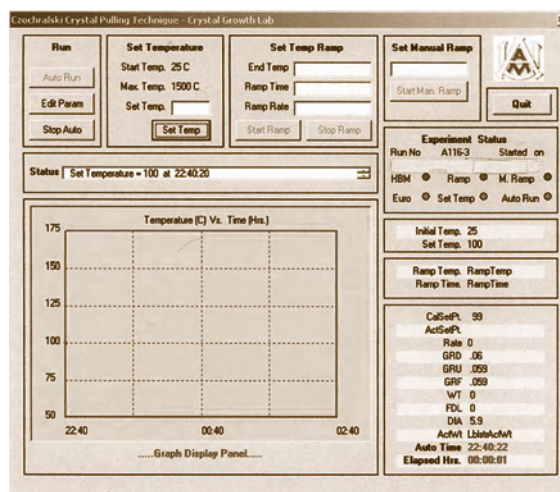

Fig. 9.6 Main parameter screen of the automatic diameter control software written in Visual Basic for the Czochralski crystal growth system

can be varied. At start up, the program asks for a history file name and parameter file to be used. After selecting the desired file corresponding to the crystal to be grown, the user enters the main parameter screen, as shown in Fig. 9.6. The main parameter screen exhibits various choices/command buttons to activate functions such as:

1. Set manual ramp
2. Ramp time
3. Ramp rate
4. End ramp
5. Edit parameter
6. Stop auto
7. Program end
8. Quit

When the *Auto* command button is pressed, it calls a subroutine to read crystal weight, calculates and displays relevant growth parameters, graphically displays temperature versus time, stores data in the history file, and sets the power level based on the calculated parameters.

In this program, one can set the desired growth profile of the crystal in terms of parameters such as seed length, cone profile, and desired crystal diameter. In the auto mode, this automatic diameter control program performs the desired functions and eventually a crystal with uniform diameter is obtained.

For a detailed description of crystal growth from melt, the text by *Hurle* is recommended [9.11].

9.4 Growth of Lithium Niobate Crystals and Its Characteristics

After more than 40 years of research into LiNbO_3 (LN), hundreds of publications have been devoted to this very important material, one of the most important photorefractive (PR) materials ever known, considering the huge number of applications it finds in our daily life.

LN is an excellent material, very attractive due to its nonlinear, electrooptic, piezoelectric, acoustical, and photorefractive properties, high electrooptic coefficient, transparency range, and the availability of large and good-quality single crystals. For these reasons, there are a huge number of applications of LN in a lot of fields such as linear and nonlinear optical devices, acoustooptic modulators, second-harmonic generation, integrated optics applications, and bulk and waveguide optoelectronic devices. In addition, LN occupies an important place in the field of laser materials, since *Johnson and Ballman* [9.12] reported for the first time pulsed stimulated emission by using Nd-doped congruent LN (Nd:CLN) crystals five decades ago.

The two principal topics that have been addressed in the last decade from the point of view of materials preparation can be summarized as the development of large stoichiometric bulk crystals and periodic structures. In the former case, CLN is commercially available, but stoichiometric LN (SLN) is still in its infancy, although there are high expectations for the Asiatic research area [9.13–15]. In the latter case, the interest emerges from LN's applications in electrooptical linear device fabrication.

CLN crystals are commercially grown on large scale by the Czochralski (CZ) method [9.16]. However it has been recognized lately that many properties of SLN crystals appear to be superior to those of CLN. The former shows larger electrooptic and nonlinear effects than those of CLN crystal [9.17, 18]. In addition, the SLN crystal coercive field has been reported to be much lower, approximately one-fifth that of CLN crystal at room temperature [9.19, 20].

Congruent lithium niobate is a very well-known material with congruent melting point and a Li/Nb ratio of about 48.6/51.4 mol %. This means that CLN is Li deficient and that Nb antisites are simultaneously present. Although these intrinsic defects represent a disadvantage of CLN which limits its technical applications, the possibility to fill these vacancies with a large number of dopants has been an extraordinary input for the applications of LN. One could say that the properties of CLN can be tailored with low concentration of a given dopant. A few examples support this statement:

active rare-earth ions allow laser action in the visible–infrared (IR) region; transition metals such as Fe and Mn increase the PR sensitivity; Ti diffusion leads to the fabrication of excellent optical waveguides; and Mg increases the resistance against optical damage. On the other hand, the applications of CLN often normally require monodomain samples, which involves an extra process for poling the initially unpoled material by applying high electric fields. These two key issues, congruency and poling processes, will be of special interest in the following paragraphs.

Stoichiometric or nearly stoichiometric lithium niobate (nSLN) is extremely important compared with CLN for several reasons: low concentration of intrinsic defects, large electrooptic coefficient, shorter absorption edge, lower coercive electric fields required for ferroelectric domain switching, lower optical damage in PR experiments, higher nonlinear optical coefficient, and lower extraordinary refractive index with constant ordinary index. Bearing in mind these properties and the future and attractive applications of SLN crystals, many efforts are being conducted towards research into this important material.

In the last decade, extensive research has been carried out in order to solve the problems related to the preparation of bulk single crystals. Now, at the beginning of the 21st century, the major scientific problems related to the preparation of bulk single crystals have been solved and now it is time for industrial developments. Below, some of the advances reported in the literature in the last decade in the field of the preparation and growth defects of LN crystals are briefly reviewed. However, we would like to remark that it would be impractical to summarize fully the large effort applied by hundreds of researchers worldwide on this topic (see, for example, two of the most recent books devoted to this material [9.1, 2]).

9.4.1 Crystal Growth of Lithium Niobate

Considering the phase diagram [9.10] and the physical and chemical properties of LN, the conventional Czochralski (CZ) growth method is practically the only way for growing bulk single crystals, and there are no significant publications related to its growth by other methods. The phase diagram is illustrated in Fig. 9.7.

The experimental conditions of the CZ method for growth of LN are well established and can be summarized as follows:

1. There are a large number of authors who use the oxide Nb_2O_5 and the lithium carbonate Li_2CO_3 as starting materials. In this case it is necessary to carry out a two-step sintering process: (1) heating at $700\text{--}850^\circ\text{C}$ for 2–12 h according to the temperature used for drying and calcination of carbonate, and (2) heating at around 1150°C for 2–4 h for sintering, followed by a grinding process at room temperature (RT) [9.21–27]. However, this process can be avoided using commercial LN of the highest chemical grade, which enables the growth of LN crystals with excellent physical properties. The same statements hold for growing other niobates or tantalates [9.27].
2. The standard growth parameters can be summarized as follows [9.23, 26, 28–34]: for CLN a pulling rate of 2–4 mm/h, with a rotation rate of 30–40 rpm, with axial temperature gradients in the solid–liquid interface (SLI) close to 10 K/cm. This value is easily attainable in resistance furnaces. However, active or passive afterheaters are recommended to be used with induction heaters. The growth process is generally terminated by a cooling process with cooling rates in the range 20–30 K/h followed by a fast cooling to RT. However some authors use an annealed step at 1000°C for 24 h to remove strains [9.30].

For SLN the pulling rate must be decreased to a value between 0.2 and 1 mm/h while the rotation

Fig. 9.7 Phase diagram of the $\text{Li}_2\text{O}-\text{Nb}_2\text{O}_5$ system for growing lithium niobate crystals

rate is in the range of 5–15 rpm. The axial temperature gradient is kept at relatively lower values compared with for CLN, while the cooling rates employed are generally the same as for CLN. As an example, Fig. 9.8 shows a schematic diagram and a picture of standard CZ equipment currently used for growing bulk LN crystals [9.35, 36]. It is also

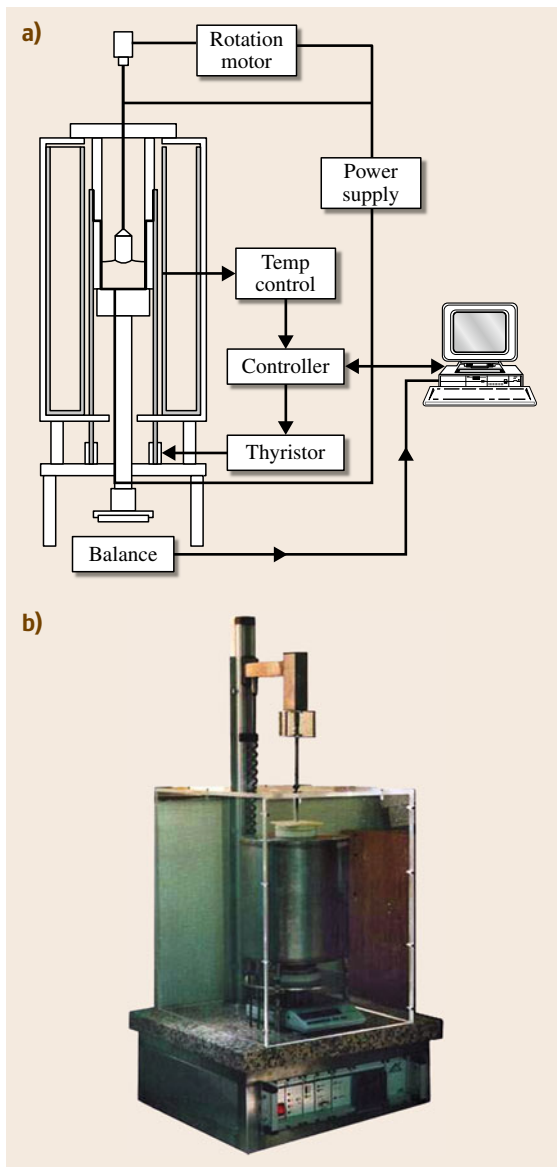

Fig. 9.8 (a) Schematic diagram and (b) conventional Czochralski crystal growth equipment with diameter control system

important to have excellent diameter control to obtain high-quality crystals. Figure 9.9 shows a CLN crystal grown by using a system like that shown in Fig. 9.8b.

3. However, the growth of bulk SLN crystals by the conventional CZ method is difficult and requires special conditions and/or technology, which are summarized in the following paragraphs.

Off-stoichiometric melts can be used with excess Li_2O in the growth process with a Li/Nb molar ratio of 1.38–1.41 [9.23–26, 30]. The yield of SLN obtained by using this process is about 10%. In this case a compositional inhomogeneity along the ingot is found, with a Li concentration difference from top to bottom in the range of 0.3–4 mol %. This inhomogeneity along the growth axis represents a great disadvantage of the off-stoichiometric melt growth process. This compositional variation increases as the Li_2O concentration in the melt increases with time.

SLN bulk crystals generally have a single-domain structure. However when an unpoled CLN seed is used in an stoichiometric melt growth, there is a diffusion of Li at high temperature from the stoichiometric melt to the CLN seed, giving rise to a compositional gradient along the length of the seed. This phenomenon induces a space-charge electric field, which in turn leads to the seed self-poling [9.37].

SLN crystals can also be successfully grown without any further experimental modification in the standard CZ technology by using K_2O -rich CLN melts. This can be considered as a mixture of oxides K_2O - Li_2O - NbO_5 where the ratio of Li/Nb is the same as that used for SLN melts [9.31, 32].

The derivative of the mass variation versus time obtained during the growth of this crystal is also shown in Fig. 9.9.

A concentration in the range 6–8 wt % of K_2O is necessary to obtain SLN crystals; other alkali oxides such as Na_2O , Rb_2O , and Cs_2O can also be used in lower concentrations, but in this case it is more difficult to obtain high-quality SLN [9.24]. The experimental conditions to be used in a K_2O -rich CLN melt growth of SLN crystals are the standard ones normally used in the CZ method. However, the rotation and pulling rates have to be low due to the higher viscosity of the melt, with values in the ranges 8–10 rpm and 0.1–0.3 m/h, respectively. The benefits of K_2O in growing SLN are related to the fact that K ions provide a similar chemical environment to that of Li ions.

It has also been proven that K is not incorporated into the crystal, while other alkali ions such as Cs and Na are entrapped in microinclusions [9.24]. Another advantage of K_2O is the lowering of the crystallization temperature close to 20°C . As a rule, all SLN crystals obtained from K_2O -rich melts have monodomain nature, with the advantage that, when using unpoled CLN seeds, they will be self-poled during the experiment [9.38].

The use of a double crucible in the CZ (DCCZ) method has proved to be an efficient approach for growing SLN, as described in [9.13, 27, 39] and references therein. The experimental setup of DCCZ is based on the use of a double crucible and/or a powder supply control in an extra upper crucible: although the experimental conditions are very strict and are generally difficult to attain in any standard crystal growth laboratory, crystals of up to 7.5–10 cm can be grown. Other benefits of this method include a constant surface melt level, which has two important consequences: constant convection throughout the growth process, and a fully stoichiometric crystal as a result of the composition adjustment of the melt supplied by the extra upper crucible. The DCCZ method is also very efficient for obtaining homogeneously doped CLN and SLN bulk crystals. Another recently developed, modified version of the double-crucible method is described in the following subsection.

Fig. 9.9 Congruent lithium niobate crystal grown using the system shown in Fig. 9.8 and the derivative of mass variation with time

9.4.2 Mold-Pushing Melt-Supply Double-Crucible Czochralski Apparatus

The double-crucible Czochralski (DCCZ) growth apparatus consisted of three parts: the double crucible, the continuous supply system, and the Czochralski growth system. The double crucible consists of a growth crucible and a melt-supplying crucible. The two crucibles are connected by some holes. The continuous supply system consists of a mold made of Pt, which is placed in the melt-supply crucible, and a lowering mechanism. When pulling the crystal, the mold is lowered to push the melt from the melt-supply crucible into the growth crucible. The lowering rate of the mold is controlled independently by the lowering mechanism; the rate is controllable and can be adjusted in real time according to the rate of change of the crystal weight. A schematic drawing of the growth apparatus is shown in Fig. 9.10. The diameter of the as-grown crystal is controlled by an automatic weighing system, which controls the heating power. The composition of the as-grown crystal is influenced by the area ratio of the cross section of the crystal to that of the mold, the compositions of the melts in the two crucibles, and the velocity ratio of crystal pulling to mold lowering. Compared with the common DCCZ method, this technique avoids the problems related to the powder supply, inconsistency of melt composition, complexity, and the high price of the growth device. Researchers into this approach called it the mold-pushing melt-supplying (MPMS) technique [9.40].

Growth of near-stoichiometric LiNbO_3 crystals was illustrated by the authors [9.40].

In this work, the purity of the raw materials (Li_2CO_3 and Nb_2O_5) was 99.99%. The Li_2O content of the melt in the growth crucible was set to be 58 mol %, whereas in the melt supply crucible it was 50 mol %. The diameter of the as-grown crystal was kept unchanged throughout the whole run, while the rate of lowering was set to be equal to that of crystal pulling. The c -axis seed crystal was rotated at 5–15 rpm and both the pulling rate of the crystal and the lowering rate of the mold were 0.5–1.0 mm/h. The melt height in the growth crucible was kept unchanged during the whole process of crystal growth by controlling the melt supply from the melt-supply crucible. The diameter of the as-grown crystal was about 43 mm. The height of the crystal was 45 mm. The crystal was clear, without inclusions, free of cracks, and light yellow in color.

Fig. 9.10 Schematic diagram of mold pushing melt supply using DC Czochralski crystal growth system

9.4.3 Congruent Lithium Niobate Crystal Growth by Automatic Diameter Control Method

The apparatus described in Sect. 9.3.7 has been used for growing lithium niobate crystals [9.7–10]. A platinum crucible is filled with 300 g LN powder (purchased from Johnson Matthey, grade 99.9999% purity). The system is heated from room temperature to a temperature above

Fig. 9.11 A lithium niobate single crystal pulled from a Czochralski crystal growth system after cooling to room temperature

Fig. 9.12 A lithium niobate single crystal after necking of the seed crystal

1260 °C during a 24 h period using ramping mode. After this, the temperature is increased at a rate of 2 K every 30 min until all the charge is molten (complete molten state is in the vicinity of 1260 °C). A 5 mm-diameter seed oriented in the $\langle 001 \rangle$ direction is dipped into the melt. At this stage, the weight of the dipped seed is monitored so that the seed does not melt, and after 2–3 h of equilibration it is slowly pulled at a rate of 2 mm/h. The

Fig. 9.13 A number of pure and doped lithium niobate crystals grown at Alabama A&M University

Fig. 9.14 Growth temperature versus time profile of the growth of lithium niobate crystal

rotation of the seed is kept at around 20 rpm. At this time the necking process begins. When the seed crystal starts to grow initially, the system is put into *Auto* mode by pressing the *Auto Run* button. After the crystal has grown to the desired size, and the crystal is withdrawn from the melt, the auto mode is stopped and the cool-down ramp is started to bring it to room temperature in 48 h. Figure 9.11 shows a grown crystal of LN being pulled out of the furnace after growth. Figure 9.12 shows a photograph of another LN single crystal along with the seed that, grown in the authors' laboratory. Figure 9.13 shows a photograph of pure and doped lithium niobate crystals.

From the history file, the growth data are analyzed, and the relevant parameters are plotted and presented

Fig. 9.15 Full diameter growth profile of lithium niobate crystal

in Figs. 9.14 and 9.15. After an initial adjustment, the power (temperature) rose during the 6 h period of growth at the diameter of the seed and then ramped down to allow the crystal to grow to its final desired diameter. The remainder of the growth shows an increase in power (temperature) due to increasing heat loss from the crystal surface. As the temperature fluctuates the automatic diameter program kicks in and controls the heat flow so that the curve of crystal diameter versus time (Fig. 9.15) is almost uniform. The irregularities in the curve represent the processing time during which the software calculates the diameter of the crystal.

9.4.4 Poling of Lithium Niobate

LN is a ferroelectric material at RT with a Curie temperature of around 1210 °C. In normal growth conditions, bulk CLN crystal has multidomain nature, while bulk SLN crystals have monodomain structure when any poling process is used. The top zone is a +Z surface while the bottom one corresponds to a -Z surface [9.30]. The origin of the internal field is related to nonstoichiometric point defects, such as lithium vacancies and niobium antisites, where hydrogen itself does not seem to play an active role [9.41]. When an external field reverses the polarization direction, the internal field tends to realign parallel to the new polarization direction with increasing temperature.

LN-based devices normally require monodomain crystals in order to eliminate undesirable multiplicity of ferroelectric domains. In order to produce poled LN crystals several techniques have been developed for use either during or after the growth process of bulk crystals. Let us summarize the most recent published results on this topic:

1. By far the most well-established poling technique is that based on the use of an external electric field applied to samples obtained from a bulk CLN ingot. For CLN, electric fields greater than the coercive field of 21 kV/mm are applied by using an appropriated mask with conductive electrodes. The process is carried out under controlled temperature of the order of 200 °C, followed by thermal annealing, and cooling of the sample while maintaining the electric field [9.25, 41–43]. The electrodes are based on a saturated aqueous solution of salts such as LiCl or KNO₃, with well-defined silicone rings. The poling process can be monitored in several ways, such as by measuring the charge delivered to the crystal,

controlling the poling current under different experimental conditions, and analyzing the switching times, domain stabilization, back-switching phenomenon, etc. [9.43]. These results are important for the design of effective recipes which can be very useful for the fabrication of more complicated domain structures. In all these applications the nature of the LN plays a key role because the switching electric field dramatically decreases with increasing Li content, in such a way that for SLN this electric field has a zero value, according to its monodomain nature [9.42].

2. The poling process in CLN crystals can be carried out in situ during the growth experiment by applying current densities in the range 1–3 mA/cm² across the growing crystal. In these experiments the seed holder acts as the negative electrode and the bottom of the Pt crucible as the positive one [9.25, 42]. The current density value is reduced when the Li concentration increases during the growth experiment, being one order of magnitude lower in quasi-SLN crystals. Moreover, small current densities help to reduce any possible problems related with the melt electrolysis and/or seed decomposition, which result in catastrophic consequences for the crystal growth. The constant current density induces a transient voltage due to the domain polarization which follows an experimental law, with a profile similar to the external shape of the crystal, which can be related to the microscopic domain polarization [9.44]. As a consequence this method can be used for growing bulk monodomain CLN single crystals along the full length of the crystal.
3. A similar approach is the poling of the whole crystal after the growth process in the same experimental CZ equipment, at temperatures close to the melting point when the remaining melt is solidified [9.22]. This process gives good results, although the use of an appropriate ratio between the applied electric field and the switching time is essential in order to prevent formation of new defects due to the high ionic conductivity at high temperature.
4. Patterned domains can also be prepared by using special techniques, for example, electron-beam writing and pulsed laser at given wavelengths below and close to the absorption edge [9.18, 45]. Both techniques have the advantage of creating ferroelectric surface domains with micro- and nanoscale dimensions, which can be analyzed in situ with appropriate microscopy facilities.

9.4.5 Periodically Poled Lithium Niobate Structures

In the last decade extensive research has been devoted to periodic LN structures. A variety of potential and promising applications have been found based on both periodic and aperiodic poled LN (PPLN and APPLN) and opposite domain LN (ODLN). Periodic structures considered as the organization of domains in a given way can be successfully applied to the fabrication of optoelectronic devices. Other structures such as ODLN, in which the polarization vector is aligned head to head and tail to tail, can be used in acoustic devices [9.46].

PPLN are structures where the polarization vector point is antiparallel, showing exceptional properties that are extremely useful for fabrication of electrooptic devices such as those conceived for the generation of light in the low-wavelength region through the quasi-phase-matched second-harmonic generation process (QPM SHG).

Although both structures, PPLN and ODLN, have extraordinary importance, we will focus our attention on PPLN structures considering the huge number of applications and possibilities for the future development of superior nonlinear optical media.

It is well known that birefringent phase-matching frequency requires single-domain crystals, while periodic-domain structures show the effect of QPM frequency conversion. These periodic modulations of the sign of the nonlinear coefficient can be obtained in ferroelectric crystals by periodically alternating the sign of the electric field of their ferroelectric domains. The benefits of PPLN structures over single-domain LN can be summarized as follows:

1. The highest value of the component of the second-order nonlinear tensor in the QPM wave-mixing process involved.
2. The reduction of photorefractive (PR) damage without the need for codoping of crystals with elements such as Mg as is the case for LN. Moreover, this SHG capability combined with LN's properties for hosting laser ions allows the development of optoelectronic devices such as self-frequency-doubling lasers, simultaneous multi-self-frequencies, and many other possibilities. Therefore, considering that the fabrication of new important devices requires microengineering of the domain structures, the first prerequisite is the manufacture of PPLN structures with controlled domain thickness.

The fabrication of PPLN structures can be performed sample by sample or just in the bulk crystal. In the former case, the most well-known and efficient technique for the preparation of these structures is the patterning of the surface by using standard optical lithography and suitable photoresist masks followed by the application of an external electric field [9.27, 47]. There are intrinsic drawbacks associated with this process: the high electric fields needed for inverting domains; domain widening due to intrinsic difficulties during the preparation of regular gratings with thickness of several μm ; preprocessing of the sample in order to prevent it from breaking; limitations in the preparation of low-period structures; problems associated with the inverted domain depth; flip-back effects in which reversed domains can revert to their original orientation when the poling field is dropped to zero; control of the poling pulse length, which must be large enough to prevent flip-back; the presence of a leakage current superimposed on the poling current; post-bake and cooling processes needed to suppress the pyroelectrically induced surface charge on the crystal surface; the thermal history of the sample prior the poling process; etc.. In spite of these problems associated with the preparation of PPLN structures by the application of an external electric field, this is the most widely used method due to the possibility of defining standard conditions to be applied in a fixed way.

A more sophisticated process for PPLN fabrication is the engineering of microdomains by applying a voltage between the tip and back electrodes in a high voltage atomic force microscope (AFM) [9.48]. The evolution of the domain generation process is similar to that of the conventional approach based on the application of an electric field. However in this AFM-based technique the nucleation begins near the charged tip working as an active nucleus center for domain formation. This process has been successfully applied to LN and TaLiO₃ structures using thick single-crystal samples.

Another interesting method for preparation of PPLN structures is off-centered CZ, which enables generation of periodic domains during the crystal growth process without applying any external electric field [9.49–52]. In this case, the formation of domain structures is related to the ratio between the rotation and pulling rates in a CZ system where the seed holder is displaced from the central symmetry axis of the furnace. Furthermore, when this ratio between the rotation and pulling rates changes during a growth process, aperiodic domains (APPLN) are formed. The off-centered CZ method is

based on the interplay between the forced convection existing in the melt and an appropriate ratio of rotation and pulling rates. Nevertheless one must also consider the effect of the **SLI**, which affects the formation of **PPLN** structure [9.53]. Furthermore, it is necessary to perform a quenching process after finishing the **PPLN** preparation, as slow cooling rates destroy the **PPLN** structures. Two advantages of this method can be mentioned. First the preparation of a large volume of **PPLN** structures, and second the ability to engineer **PPLN**-doped simultaneously with rare active laser ions and/or codoped with other interesting impurities such as Mg.

An issue which has been a matter of controversy is the domain composition in **PPLN** structures. It seems already well established that the positive domains contain higher Li concentration compared with the negative ones, which are Nb rich. In addition, the dopant concentration remains constant along the positive and negative domains, as has been proven for Nd, Er, and Y [9.54]. The influence of diffusion processes on ferroelectric domains has also been analyzed. For example the diffusion of fluorine ions along the positive domains has been ascertained by using secondary-ion mass spectrometry (**SIMS**) after a **HF** etching process [9.55]. Different etching rates between positive and negative domains have also been observed. This behavior can be understood by considering that Li outdiffusion occurs during the formation of periodic structures. This process, in turn, favors fluorine indiffusion preferentially in the positive domains, which are associated with positive charge regions as a consequence of Li outdiffusion.

Rare-earth (**RE**)-doped **PPLN** structures have additional physical properties which are advantageous for optical processes such as self-frequency doubling and self-frequency addition, as they combine nonlinear processes with host crystals containing **RE** elements [9.47, 51, 54, 56–58]. The possibility to fabricate **PPLN**-based optical devices has been proven in Er-, Nd-, and Yb-doped and Mg:Zn codoped **PPLNs**, the later two dopants being used in order to fully reduce the **PR** damage and obtain stable laser action at **RT**. However, it is also necessary to consider some drawbacks, such as the maximum limit in **RE** concentration which can be reached in the **PPLN** structures. This is the case of Er:**PPLN**, with a segregation coefficient of 1.2, where it is possible to create **PPLN** structures in the range of 0.5–1 mol %. However for lower Er concentration values irregular structures are obtained, while for concentrations higher than 1 mol %, disordered structures and clusters are formed. Similar behavior has been observed in Hf-doped **PPLN** structures, where the concentra-

tion induces polydomain structures for values higher than 0.5 mol %, or inhomogeneous structures for values lower than 0.25 mol %. This can be explained according to the Hf location in the **LN** lattice as has been previously described [9.53, and references therein]. It can be concluded that the behavior of Hf in **PPLN** structures can be considered as an exceptional case which induces a periodic modulation in Nb and Hf concentration as a function of the initial Hf concentration [9.53].

A critical issue in **PPLN** structures arises from the difficulty in visualizing them nondestructively using general techniques such as optical microscopy and low-voltage scanning electron microscopy. Nevertheless, there are other approaches which can also be used for this purpose [9.59]:

1. Considering the bulk of periodic structures as a volume diffraction grating, the use of a laser beam on a periodic structure supplies information about spatial frequency and orientation. In addition, the diffraction efficiency gives information about the magnitude of the periodic changes, where the number of diffracted spots and the spot size is the result of the properties of the domain. Light diffraction from periodic domains can be understood assuming that the refractive index changes at regions close to the domain walls, where the accumulated charge at the domain edges is probably due to the alternating Li/Nb ratio giving rise to a periodic change in the dielectric constant and hence in the refractive index of the sample.
2. Scanning force microscopy (**SFM**) has the advantage of simultaneous correlation of topographic and electrostatic images. Negative domains exhibit greater hardness, and positive ones show stronger attractive forces in the electrostatic image. Therefore, the etching rate in negative domains is faster than in positive ones. The contrast shown by the electrostatic images is explained according to the difference in the dielectric polarization, probably due to different Li/Nb ratio between the domains.

RE-doped **PPLN** and **APPLN** structures are promising materials for the development of optical devices based on nonlinear optical frequency conversion and the generation of visible laser radiation from efficient lasers operating in the near infrared. Some interesting examples of these kind of optical applications are: laser-diode pumped **PPLN**:Yb,Mg microchip laser sources; self-frequency mixing in **APPLN**:Nd [9.60]; multi-self-frequency conversion in **APPLN**:Nd [9.57], etc.

9.4.6 Doped Lithium Niobate Crystals

The main motivation for doping crystals of inorganic materials is for study of the nature of the different compounds. Fundamental questions appear in the chemistry of solids regarding the behavior of dopants during crystal growth, the charge state of these dopants, and the positions they occupy in the crystalline lattice. The modification of various physical and chemical crystal properties is also another powerful motivation for doping.

Er, Pr, Yb [9.61–66], Nd, Fe, Zn, Mg [9.67, 68], Zn [9.69, 70] In [9.71, 72], and Sc [9.73] can be considered as the most widely used dopants in LN. Most of them (Mg, Fe, Zn, In, Sc, etc.) have been studied as they are considered optical-damage-resistant elements and therefore would offer the best solution for the optical damage which severely limits the holographic storage, one of the most important applications of LN. In particular Nd is of primary importance due to its applications in laser technology. However, one of the main problems associated with LN-based continuous-wave (CW) laser oscillation technology is the difficulty in achieving this effect in these crystals (Nd:CLN). This is due to the high photorefractive damage (optical damage) which induces severe changes in the birefringence when the laser intensity is high [9.74–76]. However, it was soon recognized that this difficulty could be easily overcome by codoping Nd:CLN crystals with Mg (Nd:Mg:CLN), which successfully enables laser oscillation [9.77]. In addition an increased thermal conductivity has been reported in this material, which is advantageous even if other laser properties are almost the same.

Many studies have been devoted to the study of Nd segregation in LN crystals [9.78], through which the Nd effective distribution coefficient k_{eff} has been calculated to be 0.12. However, at relatively low Nd concentrations, Nd-doped LN normally exhibits a uniform Nd concentration along the pulling direction, enabling the growth of high-quality Nd-doped LN crystals. However the growth difficulties increase for highly Nd-doped Nd:Mg:SLN crystals.

Regarding Mg-doped LN, chemical analysis has been developed and the k_{eff} value reported for Mg in Nd:Mg:SLN crystal is 1. In addition, this value does not seem to be altered when codoping with Nd.

Some other studies have also been conducted in order to establish if CLN and SLN require the same amount of Mg in order to reduce, to the same level, the photorefractive damage. It has been demonstrated that, while 5 mol % Mg is needed [9.79] in CLN, only

1 mol % Mg is enough in SLN crystals grown from Li-rich solutions (Li-58 mol % self-flux) in order to obtain the same photorefractive damage suppression effect [9.80,81]. Lower required Mg dopant concentration has been reported for different growth methods. For example, in SLN crystal grown from $\text{K}_2\text{O-Li}_2\text{O-Nb}_2\text{O}_3$ flux [9.82], 0.2 mol % Mg is already enough to suppress the photorefractive damage. Therefore, it can be stated that Mg-doped SLN (Mg:SLN) crystals offer a great deal of advantages over congruent crystals as the difficulty to obtain high-quality crystals increases when increasing Mg doping concentration.

Doping of LN aimed at the drastic reduction of optical damage results in a secondary effect affecting the photoconductivity. This optical property drastically increases for dopant concentrations exceeding a certain threshold value [9.83]. Some recent works devoted to study of the increasing photoconductivity in LN established a relationship between this effect and a reduced Fe^{3+} electron trapping cross section which, in turn, is related to the substitutional site occupied by the Fe^{3+} ions [9.84]. In fact, laser-induced refractive index variations have been correlated to the Fe site in the LN lattice [9.85]. Extensive research has recently been conducted on these lines regarding Fe dopant in LN. For example, Zhen et al. [9.86] studied Zn:Fe:LiNbO₃ with different ZnO concentrations and several Li/Nb ratios, concluding that the optical damage increased for certain ZnO concentrations above a threshold value.

Further research devoted to the reduction of the optical damage in high-power laser applications has recently been reported [9.87]. As previously stated, due to the lower intrinsic defects in SLN, a smaller amount of MgO is enough to enhance the photorefractive damage threshold up to 2 MW/cm² [9.82]. However this is not the only type of optical damage which can be found in LN. There is another kind of damage, the so-called dark trace, which still appears in MgO-doped LN crystals. Dark trace occurs when illuminating LN with a high-power laser beam, thus limiting the potential use of this material in high-power applications. ZnO doping in LN has been reported as the solution to this problem, demonstrating the effective removal of the dark trace [9.70,87]. These authors reported that ZnO doping of SLN could increase the optical resistance to the same level reported for CLN with 4–6 mol % ZnO doping (120 MW/cm²).

Laser and holographic image recording applications have deeply motivated extensive research into Pr-doped LN [9.82–87]. However the crystal emission mechanisms of this important material are still not well

understood. In the past the quenching of the $3P_0$ population was associated with multiphonon processes. Only very recently [9.88] have other mechanisms, including exciton trapping to Pr^{3+} ions, been proposed.

Ti has also been used as a dopant in LN waveguides in order to reduce one of the well-known intrinsic drawbacks of LN when applied to the fabrication of optical modulators: the so-called direct-current (DC) drift [9.89–92]. This effect consists of the time variation of the bias voltage in an optical modulator. DC-drift characteristics are normally measured by the detection of the optical modulator output intensity. Polarization-induced space charge and ion migrations are the two driving forces inducing DC drift. The dielectric nature of LN induces electrical relaxation related to this effect. Two approaches have been used in order to reduce this effect: the first one consists of using a buffer layer over the LN waveguide; the second is mainly related to the proton impurities reduction in the LN wafer [9.93–98].

9.4.7 Relevant Properties and Characteristics

Thermal conductivity is one of the most important parameters for laser materials. High values of this physical property are desirable for laser applications. There are various methods available to determine the parameters involved in the mathematical expression for thermal conductivity, i.e., the thermal diffusivity and specific heat. Amongst these, the laser-flash method [9.97] is currently used for measuring thermal diffusivity while differential scanning calorimetry (DSC) is normally used for measuring specific heat. Thermal conductivity of LN crystals is sensitive to nonstoichiometric defects (Nb antisites). In particular, for Nd:Mg:SLN crystals it was found to be about 1.3 times as large as that of the Nd,Mg codoped congruent LN (Nd:Mg:CLN) [9.78]. These authors showed that, while density and specific heat were almost insensitive to nonstoichiometric defects (Nb antisites) and dopants, the thermal conductivity strongly depends on these two parameters.

Elastic properties have also been extensively studied in LN crystals. New methods have recently been introduced to improve the accuracy compared with early data about the elastic constants of this crystal. As an example, we can mention the work carried out by Hasse et al. [9.79], who used a novel method consisting of laser Doppler acoustic spectroscopy in order to obtain the 16 independent piezoelectric coefficients, the elastic constants, and the anelastic coefficients of LN single crystals.

Regarding the optical properties of LN, many studies have been carried out in order to ascertain the absorption and emission spectra of pure and doped lithium niobate crystals. Among these we can mention, as an example, the optical absorption and emission spectra obtained from Nd:Mg:SLN crystals which have been analyzed and compared with those of Nd:Mg:CLN crystals. The two spectra were found to be very similar to one another [9.99].

Another important measurement which is often developed in LN crystals is analysis of the OH^- absorption band, whose peak position is generally determined in order to estimate whether the resistance to photorefractive damage in a crystal is weak or not. Fourier-transform infrared (FTIR) spectroscopy is commonly used to obtain the OH^- absorption peak. In the case of Mg:CLN crystals with photorefractive damage the OH^- band peak is located at $2.87\ \mu m$. On the other hand, in the case of Mg-doped crystals without damage, it is located at $2.83\ \mu m$ [9.100, 101].

Photorefractivity is another advantageous physical property exhibited by LN crystals. This effect has been related to the hole polaron bound to Li vacancies and to three further, electronic polaronic structures, namely the free Nb_{Nb}^{5+} small (to intermediate) polaron, the Nb_{Li}^{4+} electron bound to the antisite defect, and the $Nb_{Li}^{4+}-Nb_{Nb}^{4+}$ bipolaron [9.98, 102].

Photorefractive properties in LN allow refractive index variations which can be electrooptically induced, in turn, by ionic distribution variations. These phenomena can all be used in order to permanently fix volume phase holograms recorded in LN for a long period of time, by using, for example, thermal fixing [9.103–107]. The use of the PR properties of LN for hologram thermal fixing involves three main stages. First the sample is submitted to a short heating process (a few minutes) at temperatures in the range of $120-160^\circ C$ in order to accommodate the holograms. During this process, ion migration effectively screens the initially recorded space-charge distribution. In a second stage, the ions are frozen in their new lattice positions by cooling the sample at room temperature. In the last stage, the charge distribution has to be developed by uniform illumination of the sample. Therefore fixed volume holograms can be contained by electrooptically induced variations of the refractive index generated by the above-mentioned charge distributions. Holograms lifetimes as long as 540 years have been reported recently in Fe-doped (0.1 mol %):Mg codoped (5.5 mol %) LN crystals.

The electrical conductivity of LN has also been studied for many years. It is well known that this phys-

ical property can be enhanced for concentrations of divalent ions above a certain threshold (4.5 mol %). Some researchers attributed this electrical conductivity enhancement to faster recovery or complete removal of optical damage [9.103]. Photoconductivity measurements have been developed in Cr-doped and Mg-codoped LN crystals [9.108]. In this case, the photocurrent has been explained by considering two main involved physical processes, namely, Cr^{3+}

ionization and generation of $\text{Nb}_{\text{Nb}}^{4+}$ small polarons acting as charge carriers. These experiments also showed that there exists a threshold temperature (140 K) below which photoconductivity is suppressed.

Other LN physical properties have also been shown to be strongly affected by the presence of divalent ions, such as changes in the lattice constants, and variations in the refractive indexes and in the location of the absorption edge [9.109–113].

9.5 Other Oxide Photorefractive Crystals

The list of other oxide photorefractive (PR) crystals [9.1] can be organized into two groups: pure niobates (KNbO_3 , KN), tantalates (LiTaO_3 , LTA; KTaO_3 , KTA), and titanates (BaTiO_3 , BTi), and their mixture compounds, e.g., niobates ($\text{Sr}_x\text{Ba}_{1-x}\text{Nb}_2\text{O}_6$, SBN), titanates ($\text{Ba}_{1-x}\text{Ca}_x\text{TiO}_3$, BCTi), and tantalates ($\text{KTa}_{1-x}\text{Nb}_x\text{O}_3$, KTA_N); and in the second group other PR oxides such as tellurites (Bi_2TeO_5) and germanates ($\text{Pb}_5\text{Ge}_3\text{O}_{11}$), although the importance of the former group is very well recognized due the huge number of established applications. Considering the impossibility of ordering these PR oxides according to importance, we include just a few words concerning the topics that have received the concentrated attention of researchers worldwide over the last decade.

The importance of LTA is well recognized due to their pyroelectric, piezoelectric, and optical properties. Just some brief comments about these applications:

1. Due to the unusually high electric field induced by external thermal gradients, large crystals up to 1 cm^3 have been used recently in order to induce nuclear fusion [9.114]. LTA offers the possibility to fabricate small, compact nuclear-fusion devices by using a small single crystal located in a chamber filled with deuterium gas, where a small furnace is used in order to supply heat to the crystal, creating a huge potential difference due to the pyroelectric effect. In turn, this potential is effectively used in order to accelerate the deuterium ions against a deuterated target, enabling the delivery of neutrons by nuclear fusion.
2. LTA crystals are also important for other applications such as multiplexing, demultiplexing, ultrafast optical amplifiers, and waveguide lasers [9.115–117]. However, LTA crystals are far less widespread despite the much higher optical damage threshold of LTA crystals compared with LN. Very recent

works have been devoted to exploiting the PR properties of LTA crystals for optical waveguides fabrication [9.118]. In another field, poled LTA crystals have also recently been investigated due to their potential applications in optically integrated devices [9.114].

3. Like LN, LTA crystals also show an extremely large piezoelectric effect [9.119, 120]. These physical property together with its optical nonlinearity offer great potential for fabricating sensors, transducers, actuators, etc. In particular, for acoustic applications, large piezoelectric constants and electromechanical coupling factors are required. Several recent works have been devoted to ascertaining how to improve and enhance these parameters [9.19, 121, 122].

On the other hand, SBN crystals show ferroelectricity with Curie temperatures of between 320 and 470 K for $0.25 < x < 0.73$. The ferroelectric properties of SBN critically affect their application in optical storage and light-wave amplification devices. Some studies have been conducted in order to measure the modification of their ferroelectric properties with RE doping. Following this idea an effective lowering of the phase-transition temperature T_c has been achieved [9.123, 124]. SBN also exhibits outstanding piezoelectric, electrooptic, pyroelectric, and nonlinear optical properties. In this way, amongst the many recent works on SBN on the last topic, we can mention those based on the analysis of emission and excitation spectra obtained from RE-doped SBN crystals. These studies have shown that the intrinsic disorder of the host strongly affects the spectral bands through inhomogeneous broadening [9.125]. Broad emission bands in the near infrared have also been reported for Cr-doped SBN crystals [9.126].

There are other specific features concerning the physical and chemical characteristics and properties

of the PR oxides: **LTa** is less sensitive to PR damage than **LN**, although it has the same structure with Li deficiency and a large number of Ta antisites, with a ferroelectric transition at 690 °C [9.15, 127–129]. **BTi** presents a transition at 120 °C from cubic to ferroelectric tetragonal phase, being stable at **RT** [9.1]. **SBN**, which has a lattice parameter that depends on the chemical composition of the solid solution [9.130] and a tetragonal tungsten bronze structure over a wide solid-solution range, presents a very small thermal conductivity with a value 1/60 of that of sapphire, which influences the form of the **SLI** during melt growth [9.131, 132]; **KTaN**, which shows similar valence state and ionic radius to Ta/Nb, presents difficulties for growing bulk single crystal with constant Ta/Nb ratio [9.133]; **BCTi** presents a great drawback due to the phase transition from tetragonal to orthorhombic at **RT** which deteriorates the optical quality [9.1].

Some of the preceding comments can affect the conditions of single-crystal growth, although there are a lot of similarities in the crystal growth method if one compares these PR oxides with the previous **LN** crystals. The **CZ** method, with the modifications discussed in the previous section on **LN**, is applicable to these PR oxides, although some features are specific:

- Top seed solution growth (**TSSG**) with optimized flux composition, generally in a solution rich in K_2O and in a process which requires extraordinary technical conditions, is used for **KN** [9.127].
- A variant of **DCCZ** with an automatic powder feeding system for obtaining crystals of 10 cm diameter [9.27, 129] or special parameters in the classical **CZ** method [9.128, 129] or **TSSG** with Li_2O excess [9.134] is used in the case of **LTa**.
- For **SBN** crystals a congruent composition is claimed for Sr composition of 0.61 mol % [9.135]; the double-crucible Stepanov technique with sophisticated dies is used, where the roll of the geometry of the die is fundamental to obtaining high-quality large (several cubic centimeters) crystals, although the vertical Bridgman method can exceptionally be used up to 25 mm crystal diameter [9.135], in both cases with free striations. As a consequence of the anomalous values of the thermal conductivity, a concave **SLI** is normally obtained due to the heat of solidification; a flat interface is very difficult to obtain [9.131].

- A curious method, named the step cooling technique by spontaneous nucleation, is used for **KTaN** with a gradient temperature accuracy of 0.1 K, and excess K_2CO_3 as a flux [9.133].

The growth defects that appear in **LN** crystals are still present in these PR oxides, although in a more quantitative way. In **LTa** crystals, multidomain ingots are obtained, which require a conventional poling process after growth, with a continuous core of inclusions along the crystal boule and growth defects such as twin planes, growth twins, and cracks which destroy the crystal quality [9.15, 27, 129, 136]; otherwise the importance of the seeding process and tail design seems to have a great importance in reducing the formation of mechanical twins and cracks [9.27, 129]. In **SBN**, although striations correlated with the temperature fluctuation appear, the authors claim that in general the crystals have very high optical homogeneity, are free of cracks, and have good transparency [9.20, 135, 137], although one must consider that growth by the **CZ** method is technically difficult, with highly faceted radial morphology [9.135].

The stoichiometry in PR oxide crystals is generally speaking a common characteristic considering that all of them are a mixture of more than two oxides. In **LTa** crystals there is a continuous change of Li_2O content, probably due to the Li outdiffusion from the crystal surface, an effect which is greater in near-stoichiometric crystals [9.15]. **SBN** has an open structure and the composition ratio of Sr/Ba can vary locally; considering the different ionic sizes of Sr and Ba, which gives rise to different preferred sites, its properties can be easily tailored [9.131, 132].

Doping of crystals with an appropriate impurity opens up the possible applications of PR oxides. Some singular results are the following: in **LTa**, doping with Nb helps to obtain crystals with highly homogeneous optical quality [9.136]; the PR response increases by two orders of magnitude by codoping of ZnO in **LTa:Fe** compared with **LTa:Fe** [9.128]. Some other dopants show interesting results: in **SBN** the effective coefficient of Nd is close to unity [9.137, 138]; different valence states have been analyzed by electron paramagnetic resonance (**EPR**) in **BTi** doped with Rh as well as Fe [9.1]; Bi_2TeO_5 , being a competitor for data storage applications with **LN:Fe**, is an interesting host for dopants such as Cr, V, Mo [9.1] etc.

9.6 Growth of Sillenite Crystals and Its Characteristics

The term *sillenite compounds* is applied to the series of materials which show structural similarities to γ - Bi_2O_3 . This family of compounds is very well known since the early 1970s when the first bulk crystals were grown by using CZ technique. With a structure containing Bi_2O_3 as the primary oxide compound, more than 60 single crystals have been obtained where the second oxide is a tetravalent oxide – general formula MO_2 with $\text{M} = \text{Ge}, \text{Si}, \text{Ti}$ – such as GeO_2 , SiO_2 , and TiO_2 as the most common ones. The general ratios between the two oxides is 6 : 1 and 2 : 3, giving the formulas $\text{Bi}_{12}\text{MO}_{20}$ and $\text{Bi}_4\text{M}_3\text{O}_{12}$. However this ratio can largely vary according to the phase diagram. Other $\text{Bi}_x\text{M}_y\text{O}_z$ double oxides are also known, where the cation M can be $\text{Ga}, \text{Zn}, \text{Ba}$, etc., with ratio between the two oxides different from that previously mentioned [9.139].

Bismuth sillenites $\text{Bi}_{12}\text{MO}_{20}$ (BMO, with $\text{M} = \text{Si}, \text{Ge}, \text{Ti}$ representing a tetravalent ion occupying a tetrahedral site in a body-centered cubic cell with space group I23 [9.135–137], play an important role as the main building blocks for the development of applications in the visible spectral range. These photorefractive crystals are of great importance in holographic applications, phase conjugation, and optical switching. In particular, sillenite crystals have recently found a prominent place in the field of metrology for the development of compact holographic interferometers [9.140–144]. As an example, we can mention holographic thermal fixing in $\text{Bi}_{20}\text{SiO}_{20}$ (BSO) single crystal [9.145, 146]. Extensive studies in terms of optimum dopants or thermal treatment have also been devoted to the enhancement of BMO photorefractive properties in the near infrared. This range is of great importance due to the recent development of laser diodes operating in this spectral region [9.147]. The early investigations around 1967 on the physical properties of sillenite crystals were mainly focused on congruently melting $\text{Bi}_{12}\text{SiO}_{20}$ and $\text{Bi}_{12}\text{GeO}_{20}$, and on the substitution of Si and Ge by other elements such as Ti, Ga , and Zn [9.148]. However in the last few years this research has also been directed towards the Bi_2O_3 - B_2O_3 system [9.149], where in addition to the well-known boron sillenite, there are two other compounds with relevant physical properties and applications: $\text{Bi}_4\text{B}_2\text{O}_9$ and BiB_3O_6 . The former crystallizes in the monoclinic structure (space group $P2_1/c$) and has been reported to show an extreme indicatrix dispersion [9.145]. The new material BiB_3O_6 , which crystallizes in the centrosymmetric monoclinic space group $C2$, presents extremely

good properties for effective frequency conversion devices [9.150].

Furthermore the most important sillenites used in photorefractive PR devices are those with formula $\text{Bi}_{12}\text{MO}_{20}$ ($\text{M} = \text{Ge}, \text{Si}, \text{Ti}$), so-called BGO, BSO, and BTO, respectively; those compounds, with chemical formula $\text{Bi}_4\text{M}_3\text{O}_{12}$, are relevant for manufacturing scintillator devices. Attending to the goal of this chapter, we will focus our attention on PR sillenite compounds.

BGO, BSO, and BTO are well known as good piezoelectric, excellent acoustooptic, and extraordinary electrooptic materials. In particular their high optical activity and high-speed PR response in the visible range make these materials of prominent interest. Regarding these important properties, PR sillenites are used extensively in a large number of applications: light spatial modulators, imaging treatment, hologram recording phase conjugation, optical-fiber electric field sensors, etc. Although good and excellent reviews have been published in the last decade, the last book, published by Gunter and Huignard [9.1], provides an excellent summary of the most recent and important applications of PR materials.

For these reasons, high-quality crystals with appropriate dopant concentrations are required. This is not an easy task in these compounds due to at least two main reasons that arise from the crystal growth process: the presence of a central core and the tendency for faceting. These questions will be discussed below.

9.6.1 Growth of Bulk Sillenite Crystals

The growth of PR sillenites compounds has been developed since the early 1970s. BGO and BSO have congruent melting points, while BTO melts incongruently at 875°C , where it decomposes into Bi_2O_3 and $\text{Bi}_4\text{Ti}_3\text{O}_{12}$ [9.151, 152]. In spite of this drawback in the BTO compounds growth process, very high-quality reproducible crystals have been obtained with TiO_2 concentration in the range of 8–10 mol %, with slightly different compositions amongst authors. A solid solution with a clear retrograde solidus curve has been demonstrated, and good reproducibility of the growth process can be achieved with low standard deviation of the lattice constant [9.87, 152, 153]. Several works have shown that other sillenites with cations such as $\text{Zn}, \text{Ga}, \text{Ba}$, etc. present some substantial differences compared with the common ones such as narrow temperature and compositional ranges [9.139].

The starting materials for growing sillenites are commonly oxides such as Bi_2O_3 , GeO_2 , SiO_2 , and TiO_2 . As a general rule high-chemical-quality starting materials must be used in order to avoid several problems during the growth process, and to avoid the fatal consequences that impurities in ppm amounts present in the starting materials would have in the final bulk crystal. When oxide compounds are used as starting materials, a sintering process must be developed at around 800°C for 24 h, followed by a grinding process at RT; this process is not mandatory as it could be done during the growth process, maintaining the starting products at the same temperature and for the same period of time as in the sintering process [9.154, 155]. Nevertheless, longer periods of time in the melted phase will increase the risk of evaporation of the constituent Bi_2O_3 .

A variety of techniques have been proposed for growing bulk PR sillenites crystals such as Czochralski, Stepanov, Hydrothermal, and Bridgman methods. Among these, the CZ technique is without doubt the most widely used one, with very well-established growth parameters.

Typical growth parameters for bulk BGO and BSO crystals are the followings: pulling rate 0.3–1.8 mm/h; rotation rate 10–45 rpm; temperature gradient over the melt of 10–35 K/cm; and cooling rate 15–25 K/h. Furthermore for BTO crystals the growth parameters are stricter with narrower ranges, i.e.: pulling rate 0.1–0.3 mm/h; rotation rate 10–20 rpm; axial temperature gradient over the melt 10–20 K/cm; and cooling rate 10–20 K/h [9.134, 151, 153–159]. Proper selection of the growth parameters is of primary importance due to its influence on the solid–liquid interface (SLI).

Some modifications in the CZ growth method have been published in the last decade which could be summarized as:

1. Zone melting CZ, consisting of a modified CZ technique where two crucibles are used: an outer crucible which continuously feeds the inner crucible, where the standard CZ process is followed. There are two critical steps: the adjustment of the outer crucible at the exact position for the crystal growth to reach the adequate temperature profile, and the removal of both crucibles after the process is finished [9.154].
2. A pulling down method which continuously feeds the bulk growing crystal in a similar way as is done

in the micro-pulling down method resembling the Verneuil process [9.160]; the melt is fed downwards by the action of gravity, and a molten zone is formed over the solidified material. The main difficulty in this technical approach is to obtain an adequate temperature gradient to reach a constant diameter and a controlled solid–liquid interface. Nevertheless, the great advantage is the removal of Bi_2O_3 evaporation by controlling the correct feeding.

3. The Bridgman technique is rarely used for the growth of PR sillenite compounds; nevertheless some approaches have been developed using Pt tubes encapsulated inside a ceramic tube. Al_2O_3 powder is also used between them in order to avoid thermal expansion problems which occur during the growth process [9.87]; the advantages of this modification are associated with benefits in the growth crystals claimed by the authors: lower dislocations density and striation free. Nevertheless one could say that the method is out of use compared with the standard CZ method.
4. Growth experiments in microgravity conditions [9.161] have been carried out with a similar technical Bridgman approach to the previous one and compared with the same experiments carried out on the ground; the results obtained support the ideas obtained in other recent microgravity growth experiments:
 - a) In microgravity conditions the crystallinity is better according to the results of rocking curves, which demonstrate at least two times better quality of crystals grown under microgravity conditions.
 - b) The phenomena of dewetting is observed, which is a great advantage of using the Bridgman method.
 - c) When doped crystals are studied, there is a compositional homogeneity along the ingot, with nearly constant dopant concentration, while results on the ground follow the Sheil law with variation in the dopant composition along the ingot.
 - d) Under the same experimental conditions, the solid–liquid interface is slightly convex under microgravity conditions compared with the concave one which appears on the ground.

In summary, the results of microgravity growth experiments show better perspectives than ground-based experiments.

9.6.2 Solid–Liquid Interface

The solid–liquid interface (SLI) in PR sillenites is a scientific topic which has been studied through the last decades due to its great influence on the quality of the bulk crystals. In fact, it is important to recognize that it is necessary to have complete control of the SLI in order to obtain good-quality PR sillenite crystals. Let us summarize the most important results obtained in the last decade:

1. The form of the SLI can be concave, flat or convex as seen from the melt. It is well recognized that an extremely large concave SLI will lead to dramatic consequence in the crystal such as increased stress, higher dislocations density, and microcracking; on the other hand, an extremely large convex interface will be the origin of core phenomena, which negatively affect the quality of PR sillenite bulk crystals [9.139].
2. The SLI is a consequence of the fluxes which exist in the melt, resulting from competition between free and forced convection, which are themselves governed principally by two growth parameters: the axial temperature gradient and the rotation rate; in fact, three zones must be considered: the shoulder zone, where the free convection is the dominant process and where a strong convex SLI is expected unless the rotation is drastically increased; the body zone, where the balance between forced convection and free convection must be obtained and a flat interface is normally obtained; and the last part of the growth process with a low value of the melt depth, where forced convection is dominant and a strong concave SLI is expected. All these situations have been analyzed and precisely identified by simulation tools using commercial codes [9.151].
3. The most important growth parameters that influence the SLI are: the axial temperature gradient, the pulling rate, and the rotation rate, which must be precisely controlled [9.139, 151, 153, 162, 163]:
 - a) The axial temperature gradient for crystal growth of PR sillenites is on the order of 10–20 K/cm, which is easily obtainable with resistance furnaces but very difficult to obtain with RF furnaces; in both cases the use of passive or active afterheaters is highly recommended, although the use of active afterheaters where the temperature is modified during the growth process can be more efficient.
 - b) The pulling rate must be kept within the limits discussed before, in which case its influence on the SLI is minimum.
 - c) The rotation rate is a decisive growth parameter to achieve an adequate SLI, together with the axial temperature gradient [9.130].
4. For standard growth conditions, as is normally the case in a general CZ process, the SLI changes throughout the growth process as a consequence of:
 - a) The change in crystal diameter from the shoulder to the body and from the last part to freezing
 - b) The reduction of melt height when the crystal is pulled up.

In an adequate, standard CZ process with constant rotation and pulling rates, in the initial stage of shoulder growth the SLI is convex and faceted; then this rounded shape changes from convex to flat, remaining so until a slightly concave shape is formed as the melt is reduced. These results are clearly visible when a crystal is withdrawn at different times during the growth process; furthermore simulations carried out considering specific growth parameters support these changes in the SLI [9.151, 162].
5. The consequence of a nonflat interface are thermal stresses, core phenomena, faceted interfaces, crystal cracking, impurity inhomogeneities, gas bubble entrapment, etc.
6. A flat or nearly convex interface is required to get high-quality PR sillenite bulk crystals.
7. A flat or nearly convex interface can be obtained with particular experimental conditions such as: variations in the rotation rate during the first step of the growth process during shoulder formation, a constant rotation rate during the growth of the body of the crystals, and with further variation in the rotation rate during the last part until freezing of the melt. When this situation occurs with a perfectly oriented seed crystal, we can say that we approach near-equilibrium conditions, and the result is the crystal shown in Fig. 9.16.

Furthermore, some other arrangements have been proposed such as metallic shields located on the seed holder to modify the radiation effect and as a consequence to influence the SLI [9.130, 139, 140]. Experimental results together with simulation data have shown the great influence that metallic or ceramic shields located on the seed holder have, flattening a deep interface [9.140].

From the above considerations on the SLI, two general conclusions can be drawn:

Fig. 9.16 Perfectly oriented BSO crystal obtained from nearly equilibrium conditions

1. The control of the SLI is extraordinary important to obtain high-quality crystals, and for this reason it is necessary to take special care of the growth parameters that modify the SLI, especially the axial temperature gradient and the rotation rate.
2. To obtain high-quality crystal a planar or slightly curved convex solid–liquid interface is necessary.

9.6.3 Core Effect

The core effect in PR sillenite materials has been one of the main scientific topics that have been studied for many years, due to its catastrophic consequences on the quality of crystals; see [9.139, 151, 153, 156–161] and references therein. One could say that the core effect is one of the main problems to solve in the preparation of bulk PR sillenite crystals. Let us comment on the most recent ideas which have been published in this field:

1. The core is a darker area that appears along the central part of the bulk crystal, normally full of defects and bubbles, which spreads from the shoulder part of the crystal and extends along the whole crystal, occupying a cross section of several millimeters, destroying its final crystal quality.
2. The core appears at the first stage of the growth process, just after the touching of the seed in the CZ method if no special conditions are used, a sit-

uation in the seeding process which also happens during growth by the Bridgman method in microgravity conditions, where similar defects in the core region were observed, as revealed by interferograms [9.161]. The core appears at this stage of the growth unless some conditions such as a high rotation rate are used in order to avoid the convex SLI. In fact, higher rotation rates at the shoulder position compared with the standard rotation value must be used to avoid the formation of the core region [9.156].

3. The shape of the core depends on the direction of the seed crystal. In fact when the growth direction is along the [100] and [110] directions, the core is favored and facets with several orientations are formed, while for the [111] growth direction it is easier to obtain core-free crystals for a nearly flat interface [9.157], although one must comment that there is not complete agreement between authors on this point [9.156]. Also, while for convex interfaces the core is central, for concave interfaces the core spreads out across the diameter of the crystal, forming a crown in the sample perpendicular to the growth direction; it is therefore clear that the shape of the core is related to SLI curvature [9.157, 162].
4. In general there is a consensus about the origin of the core and the relationship between the core and the facets: in some cases the core appears when there is a large convex interface at the liquid, where small facets are tangential to the interface, and in fact a faceted region is located in the core zone [9.147, 158]; in other cases, the core could be the result of small facets, and in these facets the concentration of impurities would be larger compared with the nonfacet region [9.139]. Nevertheless, it seems that in CZ growth the core effect can be avoided if one facet occupies the entire interface, which is not possible in the Bridgman method, where the core can occupy about half of the area of the grown crystal [9.139].
5. On the other hand, very recent results [9.164] show that specular reflection due to the shoulder side surface drastically changes the temperature fields and results in the appearance of a thin, cool area near the crystal axis which provokes large convexity of the SLI that may be responsible for the formation of the dark core in the center of the crystal. In this way, the angle and length of the shoulder will be of extraordinary importance for the formation of the core. In fact, experiments carried out in this regard have shown that, when a large shoulder of several

- centimeters is used and the diameter of the crystal is limited to 1 cm, the core area disappears along the whole crystal.
6. There have been several studies devoted to impurity analysis of the core. It seems that deep studies on this subject have concluded that the concentration of coloring impurities such as Fe, Mn, Ni, and Co is higher in the core, while the concentration of bleaching impurities such as Ca, Al, Mg, P, and Cl is lower [9.139]. One must indicate at this point that, when the starting materials used for crystals growth are of highest commercial quality, impurities of Fe are ever present at concentrations of a few ppm, as has been detected in the core of PR sillenites by EPR measurements. In fact EPR studies show that Fe^{3+} ions occupy the positions of Si and Ge. Also, in the growth of BSO and BGO bulk crystals, analysis of the core shows a lower concentration of the cations Si and Ge, respectively, compared with noncore regions [9.156]. For this reason one must conclude that the core in PR sillenites is an impurity-getter region.
 7. Moreover, the optical properties of the core region are different compared with those of noncore region, for example, the refractive index, which is at least five times lower in the core region [9.156]. On the other hand the cathodoluminescence emission band centered at 640 nm appears in both regions, being of higher intensity in the core region; one must therefore consider that, during electron radiation of the noncore region, the intensity of the 640 nm emission increases in intensity due to an ionized impurity such as Cr, Fe or Bi antisites as potential candidates, and as a consequence one could conclude that these emission centers are present in the core region [9.165]; for this reason one could say that in the original noncore region and under electron irradiation it is possible to create a *core* region with the same orange color and properties as the original core region.
 8. There is agreement about the influence of the shoulder angle on the formation and extinction of the core. In fact, by increasing the cone angle, the dark core is reduced, which is explained as a consequence of the flattening of the SLI, and at the same time by smoothing of T irregularities [9.157]. The consequence of this effect is very important, because if one could relate the appearance of the core to the shoulder cone, it would be necessary to strictly control the shape and angle of the shoulder in the first stages of the growth process.
 9. A general rule for the disappearance of the core is the presence of a nearly flat interface, which completely eliminates the core region [9.153, 163]. There are some other experimental conditions which reduce or eliminate the core formation:
 - a) With temperature axial gradients lower than 10°C in the vicinity of the SLI, which can be obtained either with passive afterheaters in resistance furnaces or with active afterheaters on induction heaters [9.156];
 - b) The rotation rate is probably the most critical condition, because using a critical rotation rate in the shoulder part will eliminate the core [9.156].
- In consequence, one must conclude that the core region can be avoided if some critical conditions are fulfilled.

9.6.4 Morphology and Faceting

PR sillenites can develop a polyhedral external morphology formed by the intersection of the narrow facets located at the outer part of the interface with the free surface of the melt. In fact, if special care is not taken during the growth process, such as the seed orientation, these facets are ever present and form a disordered external shape, due to this strong tendency for faceting and growth in typical habits [9.139]. Understanding facet formation during the growth process is rather complicated because there is interplay between the continuum transport phenomena and the interface growth kinetics.

The key question for the evolution of the external morphological is a balance between kinetic phenomena and thermal gradients. In fact the thermal conditions at the free surface around the crystals critically depend upon the radiant heat transfer from the melt surface and the structure of the flow field within the melt. These two conditions must be considered both in experimental conditions during the growth process and in simulation studies which can be carried out in order to understand the morphology of PR sillenite materials.

The shape of PR sillenite compounds is related to the radiative exchange that occurs during the growth process due to the growth regimes that occur throughout a complete growth experiment [9.166]. In fact, three regimes can be described:

1. During the shouldering step, radiative exchange occurs between the free melted surface and the upper surface of the growth chamber; in this case, taking

into account that the radiation losses are very high due to the low temperature of the upper surface, and at the same time considering the relatively uniformity of the radiation losses in the radial direction, both conditions will encourage a faceted exterior shape.

2. During the growth of the crystal body, the thermal losses decrease due to heat exchange between the melt surface and the growing crystal; in this case the radial gradient becomes larger, and as a consequence the crystal has a circular cross section.
3. Nevertheless, during the last part of the growth process and due to the reduced melt height, the dominant mechanism of convection is forced convection with a decrease in natural convection, which reduces the radial gradient, resulting in a crystal which exhibits a polar habit.

All three of these regimes influence the formation of a faceted crystal, and for this reason one must control the growth conditions in order to understand the appearance of facets in the crystal. Also, for a given radial temperature gradient and a nonflat interface, an induced stress appears in the growing crystal which will produce a polarization in the PR sillenite crystals in a given direction, resulting in preferential growth of facets [9.159]. In this way, considering the similar magnitude of the piezoelectric coefficients of the PR sillenites, one could conclude that these materials will exhibit similar behavior in terms of facet formation when grown under the same conditions.

Fig. 9.17 Different morphologies in sillenite crystals for different experimental conditions

There are several factors which influence the morphology and facets in PR sillenite crystals, and all of them must be considered simultaneously. One must control the rotation rate, the pulling rate, and the axial and temperature gradients, as the most important factors. In fact all of these are growth parameters that control the SLI, and for this reason one must always consider the form of the SLI. Figure 9.17 shows an example of the morphology that appears in PR sillenite crystals for different combinations of experimental conditions for pulling rate and interface shape. For example, a constant pulling rate combined with a variable rotation rate with a low axial temperature gradient will be the most adequate set of growth parameters for obtaining near-equilibrium interface kinetics in order to eliminate inversion of the morphology in such a way that the seed direction will predict the faceted crystal and the orientation of the facets in the growing crystal [9.159]. Therefore, if one controls the seed orientation and applies adequate growth parameters, one can obtain experimental growth conditions that yield near-equilibrium conditions and thereby a crystal with controlled facetting.

9.6.5 Other Growth Defects

One could say that a perfect PR sillenite crystal without growth defects is in reality a dream, after considering the previous comments about the solid-liquid interface, the core effect, and the morphology of these materials. Furthermore, there are other growth defects that must be considered, about which a few comments are given below:

1. There are always native defects in PR sillenites crystals such as Bi antisites as a consequence of the phase diagram of these compounds. Nevertheless deeper studies have shown that a complex formed by a Bi antisite and an oxygen vacancy, or even more so the same Bi antisite with an oxygen divacancy, could be the most common native defect in these materials [9.1, 167]. In fact, one cannot avoid these defects because they are intrinsic and always present, although one can increase their concentration by going outside the congruent composition in the phase diagram.
2. The presence of growth striations is related to temperature fluctuations at the interface during the growth process [9.160]. In fact, these temperature fluctuations can result in deviations from stoichiometry and variation in impurity concentration when

a dopant is used, and in some cases the appearance of metastable phases [9.139]. Furthermore, larger temperature fluctuations will create problems associated with constitutional supercooling. For all of these reasons, growth striations are problems associated with a system with segregation coefficients different from unity, and they can be measured, for example, by resulting variations in the optical density [9.130]. Nevertheless there is not a clear relationship between temperature oscillations and growth striations, as happens in other materials.

3. The use of oxides such as Bi_2O_3 as starting materials could be a source of Pt inclusions due to the high reactivity of bismuth with the wall crucible [9.139]. In fact, in single crystals obtained with completely sintered BMO materials, these Pt inclusions can be totally avoided. Nevertheless deeper studies of BSO single crystals have shown the presence of Pt inclusions in dendrite form [9.139]. Some other inclusions and large precipitates have been found after uncontrolled remelting growth originating from a process of constitutional supercooling [9.132, 168].
4. The presence of other phases with different composition is another type of inclusion that must be considered [9.139]. The most common of these is $\gamma\text{-Bi}_2\text{O}_3$, followed by Bi_2SiO_5 and Bi_2GeO_5 , although careful control of the melt temperature can eliminate these phases. It is recognized that superheating above the melting temperature on the order of 25°C is required for the growth process, with the additional benefit of eliminating other structures different from the bulk BMO. Nevertheless lower or higher superheating temperatures must be clearly avoided.
5. Another growth defect in BMO crystals is the presence of bubbles, which often appear in various zones of the crystal such as the core. The bubbles are attributed to constitutional supercooling, which often occurs when the compositional difference between the melt and the growing crystal is large, probably as a consequence of Bi_2O_3 evaporation. This circumstance can be avoided in the zone-melting double-crucible Czochralski technique due to the thin melting zone used in the growth process [9.154, 160].
6. The first method to apply to reduce the dislocation density in a bulk crystal is the use of appropriate growth parameters. Nevertheless the second approach is the use of a seed of the highest quality; otherwise, at the seed-crystal junction the original

dislocations present in the seed will propagate into the bulk crystal as individual or bundles of dislocations [9.137, 139]. For this reason, a neck is strictly necessary in PR sillenite bulk crystal growth by CZ technique.

9.6.6 Doping of Sillenites

A vast range of elements have been tried as dopants in sillenite crystals. For example Tassev et al. [9.169] reported the optical activity of $\text{Bi}_{12}\text{Si}_{12}\text{O}_{20}$ (BSO), $\text{Bi}_{12}\text{GeO}_{20}$ (BGO), and $\text{Bi}_{12}\text{TiO}_{20}$ (BTO) crystals doped with Al, P, and V and codoped with Al and P. They demonstrated important changes near the absorption shoulder in the absorption spectra of these crystals in the range of 480–590 nm. These dopants have been shown to have an important effect on the rotatory power of the crystals.

Chromium in a wide range of concentrations has also been studied as a dopant in sillenite crystals [9.170]. Extensive research has been devoted to explaining the optical absorption background [9.171] and optical activity [9.172] of Cr-doped BGO crystals. The relevance of local structure properties such as the location and local lattice distortion on the optical properties and applications has been extensively demonstrated in the literature [9.173, 174]. Strong variations in the optical and physical photorefractive properties of BTO single crystals has been reported by Mokrushina et al. [9.175] and Mokrushina [9.53], showing at least two charge states occupying probably different positions in the sillenite unit cell. This dopant shifts the absorption edge towards lower frequencies and a new absorption band appears in the near infrared when the chromium concentration in the crystals is increased.

Other rare-earth ions such as Nd^{3+} in sillenite crystals are also of primary importance for new optical devices. As a result of this promising future, Nd:BGO crystals have been widely investigated. Second-harmonic generation, optical rotation, and the fabrication of laser-diode-pumped microchip lasers are some of the challenging topics for deep study in Nd^{3+} -doped sillenites [9.173, 176–179].

Very recently some interesting studies have been devoted to the behavior of several dopants in the sillenite crystal structure, in particular when impurity ions are located at trigonal Bi^{3+} sites. As an example, we can mention recent work on dopants such as Cr^{3+} and Nd^{3+} ions in BGO crystals [9.180]. The local structures of these ions at the Bi^{3+} sites have been analyzed. It has

been demonstrated that, contrary to the general assumption that these impurities are located exactly at Bi sites, they undergo center displacements related to these sites.

Other dopants have been used in order to induce photorefractive and photochromic properties in sillenite crystals. As an example we can mention some recent works on ruthenium-doped BSO and BTO crystals [9.140, 181, 182]. Ru ions can be readily incorporated into sillenite crystals such as BSO. This ion is normally located at Bi substitutional sites, enhancing the photorefractive properties of sillenite crystals at long wavelengths (red light) [9.183].

Electrical conductivity properties in sillenite crystals have also been recently investigated. In particular, electrical properties as a function of temperature have been analyzed in BTO crystals. The results show that the electrical resistance of this material can be modeled as a thermistor with negative temperature coefficient [9.184].

9.6.7 Relevant Properties

The mechanical properties of sillenites have been studied, and the elastic constants have been determined for some sillenite crystals [9.170], including the borate sillenites. The stronger Coulomb contribution of Si^{4+} , Ti^{4+} , and Ge^{4+} compared with B^{3+} seems to be the reason why the elastic constants corresponding to boron sillenites are slightly smaller than those corresponding to Si, Ti, and Ge.

Photorefractivity occurs in photoconductive crystals with a noncentrosymmetric structure when two coherent beams are used to create an interference pattern. In illuminated areas, electrons (holes) are ionized from a defect (intrinsic or extrinsic) to the conduction or valence band of the material. Once in this state, they can move (diffusion or drift regime) to dark areas and be efficiently trapped on the same or a different defect. A space-charge field is thus created, implying a modulation of the refractive index via the electrooptic (Pockels) effect. When trapping occurs at a level different from the original one, a modification of the absorption spectrum (photochromism) is frequently observed, especially at low temperature, due to the change in the concentration of intrinsic or extrinsic defects.

Recent studies have been devoted to analysis of the influence of holes bound to acceptor defects on the optical properties of sillenite crystals. Lattice distortion generally induces a strong localization of these systems at one of the oxygen legends related to the defect. Strong and wide absorption bands, usually in the visible

region, have been reported to occur in these materials, and were related to polaron stabilization energies close to 1 eV. The formation of polarons in sillenite crystals can be characterized as follows: ideal MO_4 tetrahedra are considered as the building blocks of sillenite crystals, where M is regarded as the cation and can be Ti^{4+} , Si^{4+} or Ge^{4+} . In real samples, such as the well-known sillenite $\text{Bi}_{12}\text{MO}_{20}$ crystal, Bi antisite acceptors can be formed as a large number of the M ions can be replaced by Bi^{3+} ions. These kinds of ions present the very stable $6s^2$ configuration, which is why an electron will be taken from one of the four O^{2-} ions [9.185] instead of from the Bi^{3+} , thus forming a bound O^- polaron [9.186–188]; this is an example of where O^- is formed by direct electron ionization to the conduction band. Previous analyses [9.189, 190] have demonstrated that this defect corresponds to the localization of a hole at an oxygen site with a trigonal C_{3v} noncentrosymmetric nature in the paramagnetic state. Therefore space charges generated by inhomogeneous illumination are transposed into refractive index changes via the Pockels effect. This photorefractive effect shows quite a fast response to illumination variations, mainly related to the high mobility of the electrons in the conduction band, forming large polarons [9.191].

All of the statements above show that the main intrinsic absorption of the sillenites, causing their typical honey-yellow coloration, is due to charge transfer excitations of an O^- bound polaron next to Bi^{3+}M antisite defects [9.60]. Very recently, the Bi-richest sillenite, $\text{Bi}_{24.5}\text{BO}_{38.25}$, has been successfully grown by the TSSG method [9.170]. The high values obtained for the refractive indexes of this boron sillenite compared with silicon sillenites were attributed to its high Bi content.

As previously mentioned, BSO [9.192] can be used for holographic applications. Hologram thermal fixing in BSO is induced by hydrogen impurities. This BSO material exhibits some differences compared with other crystals such as Fe-doped LN, including higher fixing temperatures (220 °C in BSO versus 140 °C in Fe:LN) and higher activation energy (1.44 eV) compared with Fe-doped LN (0.95 eV) [9.145, 146]. As a result, thermally fixed room-temperature lifetimes in BSO are much longer than those of holograms recorded in LN. Holographic fixing has also been achieved in other sillenites, such as BTO [9.193]. In this case, the fixing method consisted of the application of an alternating-current (AC) field under simultaneous heating at 90 °C. Two key material properties in holographic technology are: (1) high enough diffraction efficiencies and

(2) fast responses for processing of unfixed holograms. In this sense, sillenites are very promising materials for practical holographic applications, as long extrapolated hologram lifetimes of 10^4 years have been reported for particular materials such as BSO crystals [9.145].

9.6.8 Growth of Photorefractive Bismuth Silicon Oxide Crystals

For a typical $\text{Bi}_{12}\text{SiO}_{20}$ single-crystal growth run, 6 moles of Bi_2O_3 and 1 mole of SiO_2 (522.9 g of Bi_2O_3 and 11.237 g of SiO_2) are thoroughly mixed and loaded into a platinum crucible that is 5 cm in diameter and 5 cm high. The charge of 534.1 g is calculated to fill the crucible to 1.25 cm below the top with molten $\text{Bi}_{12}\text{SiO}_{20}$. From the phase diagram (Fig. 9.18), the melting point of $\text{Bi}_{12}\text{SiO}_{20}$ is about 910°C [9.10]. The charge is then melted at around 920°C in an induction furnace and the remaining material is loaded into the hot crucible. After all the material has been added, the charge is allowed to remain molten for 20 h. A seed crystal is slowly lowered to touch the melt surface in the center of the crucible. The seed is rotated at between 10–20 rpm and, for best results, pulled at between 2–2.5 mm/h.

If the interface is flat and the boule is a great deal smaller in diameter than the crucible, the interface will be elevated above the mean height of the melt and a column of liquid will be weighed along with the crystal. In

the more common case of oxide crystals, the interface is not flat but rather convex toward the melt and the boule diameter is > 0.5 times the crucible diameter.

Thus, part of the interface extends below the level of the melt and that part of the solid is buoyed up by the liquid so that the measured weight is less than that of the crystal.

In both cases, however, the shape of the melt surface is not flat near the crystal and near the crucible wall. If the melt wets the solid crystal, the melt surface will rise to come into contact with the solid at a small angle, leaving a concave curved ring of liquid above the mean surface of the melt. If the melt does not wet the solid, the curvature is convex and the melt surface is lowered to a level near the surface of the solid.

From above, the surface of the melt appears to have a particular temperature due to the actual temperature of the melt and the additional influences of the radiation from the bulk of the melt and the inner surface of the crucible containing the melt. Both are modified by the emissivity of the liquid surface, the reflection of ambient light (if any), the reflectivity of the liquid surface, and the angle of incidence of the ambient light.

For the flat portion of the melt surface, the contribution of ambient reflections is quite small since the light would have to come from the (relatively cold) top of the furnace setup. However, if the surface is curved concavely, light is reflected from the inside of the crucible

Fig. 9.18 Phase diagram the Bi_2O_3 - SiO_2 system for growth of $\text{Bi}_{12}\text{SiO}_{20}$ crystals

Fig. 9.19 BSO crystal grown using automatic control at Alabama A&M University

wall above the melt level, which is the hottest part of the growth environment. Thus, the meniscus wetting the growing crystal should appear hotter than the flat melt surface. If the melt does not wet the solid, the meniscus is convex and will reflect the crystal surface above it, which is colder than the melt and generally has a lower emissivity than the liquid. Thus the ring in this case should appear darker than the flat melt surface.

Radiative heat loss (proportional to the fourth power of the temperature) produces large temperature gradi-

ents in the crystals as they cool from their melting point, resulting in thermal stress that can result in shattering of the crystal some time after it has reached room temperature. These effects are minimized by the use of afterheaters.

Typical dimensions of successfully grown BSO crystals are 22 mm diameter and 75 mm long, and their typical weight is 250–300 g. A photograph of a BSO crystal grown using automatic diameter control is shown in Fig. 9.19.

9.7 Conclusions

The principal circumstances relating to the bulk growth of the photorefractive materials lithium niobate (LiNbO_3) and sillenites have been reviewed. Both of these kinds of crystals are grown by Czocharlski method, with similar problems originating from similar effects. This implies that they have similar solid–liquid interface and other crucial growth parameters. In LiNbO_3 the two most important problems to solve are their stoichiometry and the growth conditions to obtain periodic structures, which have been practically solved through interesting research solutions. Lithium niobate has an extensive array of properties that have made it one of the most widely used ferroelectric materials, with one of its major applications being the manufacture of surface acoustic wave devices, employed in high-speed signal filtering in televisions and mobile phones. In fact,

this material is often dubbed the silicon of nonlinear optics. It is widely sought after for applications for acoustic wave transducers, optical amplitude and phase modulators, second-harmonic generators, Q-switches, beam deflectors, phase conjugators, optical waveguides, holographic memory elements, and holographic data-processing devices. In sillenites, there is still a long way to go to reach the final goal of obtaining large high-quality bulk crystals, because problems inherent to their physicochemical properties such as the core effect and the solid–liquid interface are ever present. However, it can be seen that, in the last decade, there have been a large number of publications and an extraordinary high level of effort with the final result that most of these problems have been solved, as summarized in this chapter.

10. Bulk Crystal Growth of Ternary III–V Semiconductors

Partha S. Dutta

Ternary semiconductor substrates with variable bandgaps and lattice constants are key enablers for next-generation advanced electronic, optoelectronic, and photovoltaic devices. This chapter presents a comprehensive review of the crystal growth challenges and methods to grow large-diameter, compositionally homogeneous, bulk ternary III–V semiconductors based on As, P, and Sb compounds such as GaInSb, GaInAs, InAsP, AlGaSb, etc. The Bridgman and gradient freezing techniques are the most successfully used methods for growing ternary crystals with a wide range of alloy compositions. Control of heat and mass transport during the growth of ternary compounds is crucial for achieving high-quality crystals. Melt mixing and melt replenishment methods are discussed. The scale-up issues for commercial viability of ternary substrates is also outlined.

10.1 III–V Ternary Semiconductors

Ternary compounds are synthesized by mixing three elements. These are also referred to as pseudobinary or tertiary compounds or alloys. From the periodic table, one can mix two group III elements and one group V element to form ternaries such as $\text{Ga}_{1-x}\text{In}_x\text{As}$. Alternatively one could mix one group III element and two group V elements to form ternaries such as $\text{InP}_{1-y}\text{As}_y$. Here x and y are mole percentages. The values of x and y are between 0 (0 mol %) and 1 (100 mol %). *Pseudobinary* is an equivalent term since a ternary compound such as $\text{Ga}_{1-x}\text{In}_x\text{As}$ can be viewed as comprising of x mol % of InAs and $(1-x)$ mol % of GaAs. Ternary compounds are attractive as substrate materials for electronic and optoelectronic applications since one can tune the lattice parameter or the bandgap energy of the ternary materials by choosing appropriate chemical compositions [10.1–7].

Figure 10.1 shows the lattice parameters and bandgap energies of the III–V semiconductors [10.1]. The values of bandgap and lattice parameter of the binary compounds such as GaAs, InP, GaSb, InSb, etc. are based on experimental data. Curves joining two binary compounds would represent different ternary compounds. For example, a curve between GaAs and InAs would represent the ternary $\text{Ga}_x\text{In}_{1-x}\text{As}$ ($0 < x < 1$) compound. The curves shown in the literature are primarily extrapolated based on experimental data points of few alloy compositions.

The lattice constants of ternary compounds (a_t) varies linearly with composition (x) between the two

binary lattice constants (a_1 and a_2). This is known as *Vegard’s law*

$$a_t = xa_1 + (1-x)a_2 \tag{10.1}$$

For example

$$a(\text{Ga}_{1-x}\text{In}_x\text{As}) = x a(\text{InAs}) + (1-x)a(\text{GaAs}) \text{ .}$$

The lattice constants for binary compound semiconductors are listed in Table 10.1.

The bandgap of any ternary compound varies non-linearly with the alloy composition (x or y). The

Table 10.1 Lattice constant, direct (D) and indirect (I) bandgap energy, and corresponding wavelength for As-, P-, and Sb-based III–V binary semiconductors

Material	Lattice constant (Å)	Bandgap energy (eV)	Bandgap wavelength (μm)
AlP	5.467	2.45 (I)	0.50
AlAs	5.660	2.14 (I)	0.58

Table 10.2 Dependence of bandgap on alloy composition for As-, P-, and Sb-based ternary semiconductors

Alloy	Direct energy gap (eV)
$\text{Al}_x\text{In}_{1-x}\text{P}$	$1.34 + 2.23x$
$\text{Al}_x\text{Ga}_{1-x}\text{As}$	$1.424 + 1.247x, 0 < x < 0.45$ $1.424 + 1.087x + 0.438x^2, x > 0.45$
$\text{Al}_x\text{In}_{1-x}\text{As}$	$0.356 + 2.35x + 0.24x^2$
$\text{Al}_x\text{Ga}_{1-x}\text{Sb}$	$0.726 + 1.10x + 0.47x^2$
$\text{Al}_x\text{In}_{1-x}\text{Sb}$	$0.18 + 1.621x + 0.43x^2$
$\text{Ga}_x\text{In}_{1-x}\text{P}$	$1.34 + 0.511x + 0.6043x^2, 0 < x < 0.55$
$\text{Ga}_{1-x}\text{In}_x\text{As}$	$0.356x + 1.425(1-x) - 0.436x(1-x)$
$\text{Ga}_{1-x}\text{In}_x\text{Sb}$	$0.18x + 0.726(1-x) - 0.415x(1-x)$
$\text{GaP}_x\text{As}_{1-x}$	$1.424 + 1.172x + 0.186x^2$
$\text{InP}_x\text{As}_{1-x}$	$0.356 + 0.675x + 0.32x^2$
$\text{InAs}_y\text{Sb}_{1-y}$	$0.356y + 0.18(1-y) - 0.58y(1-y)$
$\text{GaAs}_y\text{Sb}_{1-y}$	$1.424y + 0.726(1-y) - 1.2y(1-y)$

Fig. 10.1 Lattice constant, bandgap energy, and corresponding wavelength for As-, P-, and Sb-based III–V binary semiconductors

experimentally measured bandgap (E_g) for a ternary alloy can be fitted to a quadratic equation [10.1]

$$E_g(x)[\text{eV}] = xE_1 + (1-x)E_2 - cx(1-x), \quad (10.2)$$

where E_1 is the bandgap at $x = 1$, E_2 is the bandgap at $x = 0$, and the *composition independent* constant c is the bowing parameter accounting for the nonlinearity.

The above equation (10.2) can be rearranged as

$$E_g(x) = a + bx + cx^2,$$

where

$$a = E_2, \quad b = E_1 - E_2 - c, \quad c = c.$$

Table 10.2 summarizes the bandgap equations for various III–V ternary compounds. The bandgaps and lattice parameters shown in Fig. 10.1 as well as listed in Tables 10.1 and 10.2 are for compounds with the same crystal structure (zincblende or cubic). If the crystal structure changes, the lattice parameter and bandgap of the same material will be different. For example, the II–VI compound ZnS can exist in hexagonal or cubic phase.

10.2 Need for Ternary Substrates

For most semiconductor devices, multilayered thin-film structures comprising various ternary and quaternary compounds (also known as heterostructure) are necessary (Fig. 10.2). Ideally one would like to grow the entire thin-film structure on a substrate with same lattice constant (referred to as lattice-matched substrate). Unfortunately, device-grade single-crystal substrates of only binary compounds (such as GaAs, GaSb, InP, GaP, InAs, and InSb) with a few discrete lattice constants are commercially available (Fig. 10.1). Hence thin epitaxial layers are grown on binary substrates using liquid-phase epitaxy (LPE), metalorganic vapor-phase epitaxy (MOCVD or OMVPE) or molecular-beam epitaxy (MBE) techniques, as shown in Fig. 10.2. Due to the lattice mismatch between the epilayer and the

substrate, misfit dislocations originate at the growth interface and propagate into the device layers [10.1, 8]. Typical misfit dislocation density is in the range of 10^6 – 10^9 cm^{-2} [10.8]. Such a high density of dislocations leads to degradation of the electrical and optical characteristics of the devices. To reduce this misfit dislocation density, a variety of buffer layers are grown between the substrate and the device layers. However, the buffer layer technology necessary to relieve misfit-related stresses is not optimized for all systems, and often devices exhibit poor characteristics due to interfacial defects. Hence substrates with variable lattice constants are highly desirable to enhance the performance of electronic and optoelectronic devices.

The availability of substrates with tunable bandgap and lattice constant would also open up numerous possibilities of interesting bandgap engineering in homo- and heteroepitaxial devices with improved performances, new features, reduced fabrication complexity, and better cost effective. Some appropriate examples are: GaInAs laser diodes on lattice-matched substrates with high characteristics temperature [10.9–11], low-cost, high-quantum-efficiency photodetector [10.12, 13], and thermophotovoltaic cells [10.14] with diffused p-n homojunction on GaInSb bulk substrates, high-efficiency tandem solar cells [10.15], and antimonide-based quantum well and superlattice structures lattice matched to GaSb for high-efficiency mid-infrared sources and detectors [10.16]. Future devices with improved performances are being sought for a variety of military and civilian applications. These include: infrared (IR) imaging sensors for missile and surveillance systems; IR sources for deceptive jamming system; monitoring and detecting environmental pollution, fire, greenhouse-gas fluxes, industrial gas purity, trace moisture in corrosive

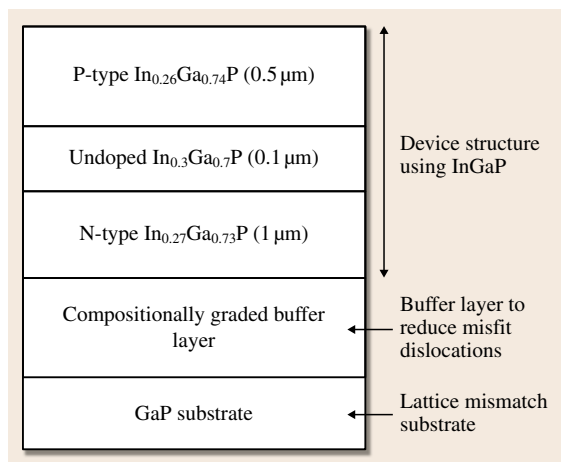

Fig. 10.2 A typical III–V ternary-based optoelectronic device structure grown on a lattice-mismatched binary substrate using a compositionally graded buffer layer

gases, and microleaks of toxic gases; high-performance and economical off-grid heat-electricity cogeneration systems; automobiles with ultralow emission (hybrid fuel–thermophotovoltaic); high sensitivity piezosensors and actuators; and quantum computing using electron spin coupling. Ternary substrates will provide a broad base of multicomponent alloy semiconductors with compatible heterostructure devices for these applications.

Bulk single-crystal substrates of ternary semiconductors are still not available from any commercial

vendor in spite of four decades of research on ternary substrates. The reason is not due to the lack of market for these substrates, but due to inherent problems in growing them from melt [10.17–31]. The development of electronic, optoelectronic, and photovoltaic devices based on ternary lattice-matched substrates has not been successful due to the poor substrate quality of mixed alloys and/or low yield of wafers with the same alloy composition. This chapter lays out the challenges and potential solutions that could be adopted for future commercial development of ternary substrates.

10.3 Criteria for Device-Grade Ternary Substrates

For successful incorporation of ternary substrates into future commercial device technologies, the wafers need to meet several important criteria as discussed below:

- (a) Single crystal wafers of 2 in (50 mm) or larger diameter must be available. Most commercial epitaxial growth and device fabrication equipment is geared towards handling wafers of 50 mm or larger. Hence the growth and fabrication conditions for any specific device structure need to be optimized using the geometries that will ultimately be used in large-scale production.
- (b) The spatial compositional inhomogeneity across the entire wafer should be minimal (less than 0.5 mol %). Variations in composition will lead to differences in final device characteristics fabricated across the wafer.
- (c) Wafers should be completely free from cracks, metallic inclusions, and multiphase regions. These are commonly observed defects in ternary crystals and hence a great deal of care is necessary to avoid them during growth.
- (d) The dislocation density should be similar to that in existing high-quality commercial binary substrates (less than 1000 cm^{-2}). Since the dislocations in the substrate propagate into the epilayers, lower dislocation density in the starting wafer is always desirable for better yield of reliable devices [10.1].
- (e) A wide range of doping should be possible in the substrate material in order to achieve desirable optical and electrical properties [10.32–38]. For electronic devices, semi-insulating substrates are necessary. For infrared photodetector applications with back illumination (radiation incident from the back of the substrate) or for light-emitting diodes, the substrate must be optically transparent for wavelengths that are being detected or emitted in the epilayers. The electrical resistivity or optical transparency can be altered by suitable impurity doping of the bulk crystal. Even if lattice matching is achieved using a certain substrate material, if they do not have the necessary electrical or optical characteristics, the substrates are of little use for end applications. For example: high-purity undoped substrates of GaSb are completely opaque for radiation with wavelengths less than its bandgap [10.35–37]. This is due to large concentration of native defects such as vacancies and antisites in the grown crystals. These defects act as p-type dopants, leading to optical absorption by free carrier mechanisms and low electrical resistivity. High-resistivity (semi-insulating) GaSb substrates are not commercially available. The optical transparency of GaSb (for below bandgap radiation) as well as its resistivity can be enhanced by impurity compensation [10.32, 37].
- (f) Ternary crystals tend to be brittle than binary crystals and can be damaged during wafer slicing and polishing. This is due to high built-in strain in the crystals. Ensuring that the crystals can be processed into wafers is crucial. This requires proper thermal conditions during crystal growth and postgrowth annealing treatments.
- (g) The wafer should have high-quality polished and chemically treated surface to enable epigrowth (also referred to as *epiready* surfaces) of high-quality layers. Certain materials such as AlSb, even if available as high-quality substrates, cannot be easily adopted for epigrowth or device fabrication due to the challenges with the surface oxidation. Similarly, antimonide-based wafer surfaces such as GaSb or

InSb need special chemical processing before growing device-quality epilayers. Hence developing the polishing recipe for each substrate material is necessary for their application.

- (h) Finally, the cost of the final wafers should not be significantly higher than that of commercially available binary substrates. Though bulk substrates contribute to a small fraction of the cost for the entire device, high cost of the substrates poses a barrier for adoption unless it is clearly established that, by using lattice-matched substrates, significant improvements in device characteristics can be achieved.

These attributes can be translated into numerous constraints during crystal growth. As will be discussed in this chapter, many of the requirements are counteractive, and appropriate trade-offs in the growth conditions are necessary.

The growth conditions that are necessary for high-quality ternary crystals have been summarized below:

1. Crack-free and inclusion-free crystals can be grown by avoiding constitutional supercooling. That means that the crystal growth rate must be lower than the rate at which excess constituents rejected at the melt–crystal interface (due to segregation) are mixed back into the growth melt. This requires forced convective mixing in the growth melt and near the melt–crystal interface.
2. Low dislocation density and strain can be achieved if the growth takes place under a low temperature gradient and the crystals are cooled slowly after solidification.
3. High yield refers to obtaining wafers of the same composition from a single ingot. This is possible only when the crystal grown has the same composition along the growth direction. This requires replenishment of the melt with the constituents to maintain the same melt composition during the entire growth.
4. Rapid or uncontrolled melt replenishment leads to high level of supersaturation in the melt with the replenished constituents. This triggers polycrystalline growth due to random nucleation in the melt. To maintain single-crystallinity during growth, the rate at which the solute is fed to the melt must be precisely controlled at all times to match the crystal growth rate. This requires special solute feeding processes and forced convective mixing in the melt.
5. Low cost of final wafers directly relates to the growth rate of the crystal and the volume of starting melt versus the volume of final crystal. This would require: (a) consuming the entire melt during the growth and (b) rapidly transporting the dissolved constituents (replenishing elements or compounds) to the growth interface by forced convection. In addition, rapid dissolution of the replenished constituents (solute) is necessary. This would require that the dissolution of the solute occurs in a melt zone that is always undersaturated.
6. Compositionally homogeneous wafer would translate to uniform composition in the crystal perpendicular to the growth direction. This would require a planar melt–crystal interface during growth. This can be achieved by balancing the heat transfer at the melt–crystal interface by a combination of temperature gradient imposed by the furnace and the forced convective mixing in the growth melt. At the same time, temperature fluctuations due to forced convection in the growth melt (leading to composition fluctuation and local constitutional supercooling) must be eliminated. This can be achieved by having a low temperature gradient near the liquid–solid interface.
7. Large-diameter wafers are necessary for commercial applications. Hence any technology that is being developed for growth of alloy semiconductors must scale up to dimensions required for practical usage. This would require optimization of the heat and mass transport processes between various melt zones during growth for the length scales of interest. This is purely dictated by the design of the experimental setup and the process parameters. Bridgman and gradient freezing types of method are becoming more popular for large-diameter binary crystal growth with very low defect content. Hence the advancement made for binary growth could be adopted for future ternary crystal growth technology.

To achieve these goals, a lot of effort in engineering of the heat and mass transport processes during the growth of ternary alloys from melts is necessary. In this chapter, we discuss the interdependencies between various experimental parameters and their effects on the compositional homogeneity of ternary crystals. The focus will be on the Bridgman techniques as it offers a variety of beneficial attributes that are necessary for ternary crystal growth processes. In the next section, we briefly review the Bridgman and gradient freezing directional solidification processes.

10.4 Introduction to Bridgman Crystal Growth Techniques

10.4.1 Bridgman Techniques

The Bridgman technique (also referred to as the Bridgman–Stockbarger method) is one of the oldest techniques used for growing crystals [10.39]. The crystal growth can be implemented in either a vertical (vertical Bridgman technique) or horizontal system configuration (horizontal Bridgman technique). Schematics of the two configurations are shown in Figs. 10.3 and 10.4. The growth systems typically consist of a single- or multizone furnace. A single-zone furnace has a parabolic temperature profile with the highest temperature being at the center along the length of the furnace, as shown in Figs. 10.3 and 10.4. On both sides of the hottest section, a temperature gradient exists that is used during the crystal growth. For a multizone furnace, specific temperature gradients between different zones can be established as described later.

The principle of crystal growth using Bridgman technique is based on directional solidification by translating a molten charge (melt) from the hot to the cold zone of the furnace, as depicted in Figs. 10.3 and 10.4. The presence of a seed at the end of the crucible (container) ensures single-crystal growth along specific crystallographic orientation. The process for generat-

ing the *first* single crystalline seed of any new material has been described in Sect. 10.4.3. Using the single-crystal seed, the entire growth process takes place in the following sequence. At the beginning of the experiment, the crucible with the polycrystalline charge and seed is placed inside the growth chamber. Then the chamber is evacuated by a vacuum pump and refilled with inert gas. The temperature of the furnace is then raised. A proportional–integral–differential (PID) control mechanism controls the power to the heater elements, maintaining the desired temperatures. The PID controller also controls the power during the heating and cooling stages of the furnace. After the furnace is heated to a temperature above the melting point of the polycrystalline charge, the crucible is slowly translated into the hot zone to melt the polycrystalline charge completely and bring it into contact with the seed. Section 10.4.4 presents the intricacies of the seeding process. After the melt touches the seed, a portion of the seed is remelted to expose a fresh growth interface. The melt is thoroughly mixed using forced convection generated by rotating the crucible (using stepper motor control, for example). The homogenization of the melt can also occur by natural convection and diffusion in the melt without any forced convection. Hence melts can be homogenized by simply leaving the melt at temper-

Fig. 10.3a,b Schematic diagram of a vertical Bridgman (VB) crystal growth process in a single-zone furnace: (a) at the beginning of the experiment and (b) with partially grown crystal

Fig. 10.4a,b Schematic diagram of a horizontal Bridgman (HB) crystal growth process in a single-zone furnace: **(a)** at the beginning of the experiment and **(b)** with partially grown crystal

atures higher than its melting point for a long duration. After the melt is completely mixed, crystal growth is initiated by cooling the melt from the seed end. This is done by translating the crucible slowly into the cooler section of the furnace. As the crucible is translated, the temperature at the bottom of crucible falls below the solidification temperature (the melting point of the material) and hence the melt starts to become a solid at the bottom of the crucible (at the seed–melt interface). After the melt has been completely translated below the melting point of the material, the entire molten charge converts to a solid ingot (also known as a boule). The crucible holder (typically made out of graphite) is connected to a stainless-steel shaft, which in turn is connected to a linear slide operated with the use

of a computer-controlled stepper motor assembly. The computer program controls the lowering rates of the crucible, and hence the rate of crystallization (growth rate) can be accurately controlled over long periods of time.

The growth rates for different crystals need to be optimized in order to grow single crystals with high crystalline quality. For example, the typical growth rate for III–V binary semiconductors is in the range of 0.5–3 mm/h, while for ternary crystals it is in the range of 0.1–1 mm/h. The shaft supporting the crucible can also be rotated with the help of a high-torque stepper motor. As will be discussed later, this is essential for efficient mixing of the melt during growth. After the entire molten charge is directionally solidified, the temperature of the furnace is decreased slowly to reach room temperature. The postgrowth cooling rate must be controlled in order to avoid thermal shock (due to rapid cooling) to the solid ingot that could lead to mechanical cracks in the crystal. Typical cooling rates are in the range of 10–50 °C/h, depending on the material. At the end of the experiment, the crystal is removed from the crucible and sliced to prepare the substrates. Figure 10.5 shows a typical vertical Bridgman grown ingot of GaInSb from the author's laboratory.

Though the concept of vertical and horizontal Bridgman techniques is similar, there are certain advantages and disadvantages of the two methods. The wafers extracted from vertical Bridgman grown crystals are perfectly circular in shape, unlike the D-shaped wafers from horizontal Bridgman grown crystals. For

Fig. 10.5 Vertical Bridgman grown $\text{Ga}_{1-x}\text{In}_x\text{Sb}$ single crystal (from the author's laboratory)

large-scale epitaxial growth on the substrates and device fabrication, circular wafers are certainly beneficial. The primary advantages of the horizontal Bridgman grown crystals are the high crystalline quality (such as low dislocation density) of the crystals and the stoichiometry control along the entire length of the crystal. In the horizontal Bridgman method (Fig. 10.4a,b), the crystal experiences lower stress due to the free surface on the top of the melt. During the growth, the solid does not touch the crucible on the top and hence is free to expand. Another advantage of the horizontal growth process is the enhanced mixing in the melt due to thermal convection (flows due to temperature gradient) at every location in the melt along the growth direction. As will be discussed later, this helps in ensuring stoichiometry (the composition of the crystal) along the length of the crystal by maintaining an overpressure of the volatile species such as the group V elements during III–V semiconductor growth.

Finally, it must be mentioned that, in the Bridgman techniques, the relative motion between the crucible and the furnace is all that matters. Instead of using crucible translation, the crucible can be kept stationary and the furnace translated to achieve directional solidification. In numerous cases, the crucible system design containing the melt, seed, and the overpressure elements is complex (as will be discussed below for GaAs and InP crystal growth) and hence translating the crucible poses

problems. It becomes much easier to translate the furnace along the crystal growth direction. The gradient freezing techniques discussed below is a sophisticated method to achieve the same effect without translating the crucible or furnace.

10.4.2 Gradient Freezing Techniques

The gradient freezing technique is analogous to the Bridgman technique discussed above except for the fact that the temperature gradient is translated along the melt to implement directional solidification [10.40–44]. The schematic of the gradient freeze method is shown in Fig. 10.6. The principle can be implemented in either vertical (VGF) or horizontal (HGF) configurations, as in the case of Bridgman methods. In the gradient freezing techniques, the crucible with the seed and the melt as well as the furnace system is kept stationary. The temperature gradient, as shown in Fig. 10.6, is moved along the crystal growth direction starting from the seed–melt interface to the end of the crystal. This is accomplished by a multiple-zone furnace system wherein the power to each zone is programmed and controlled by individual PID controllers. The use of multiple heater zones is necessary to maintain the same temperature gradient at the melt–solid interface during the entire crystal growth experiment. If a single-zone furnace is used, the temperature gradient at the

Fig. 10.6a,b Schematic diagram of a vertical gradient freeze (VGF) crystal growth process in a multizone (eight-zone) furnace: (a) at the beginning of the experiment and (b) with partially grown crystal

melt–solid interface changes at different locations in the furnace leading to variation in crystal growth rate with time. Since the heat flux through the growing crystal and melt changes with time, the multiple-zone system ensures continuously varying power to individual zones so as to maintain the same temperature gradient at the liquid–solid interface. The quality of the crystals grown by this method is far superior to that produced by traditional methods such as liquid encapsulated Czochralski (LEC). Since LEC growth takes place under a large temperature gradient (typically several tens of °C/cm), the dislocation density in grown crystals is of the order of $10\,000\text{ cm}^{-2}$ [10.1, 42, 45]. Wafer breakage in the device production process due to large thermal stress in the wafers is a significant problem. On the other hand, the temperature gradient used in the Bridgman or gradient freezing methods is very small ($1\text{--}10\text{ °C/cm}$). Hence a dislocation density less than 500 cm^{-2} has been achieved in VGF-grown crystals. As a result of this, the VGF and HGF techniques have received widespread commercial usage for both III–V and II–VI semiconductor crystal growth [10.40–44].

In a typical crystal growth experiment, the crucible with the charge is placed in the growth chamber. Then the chamber is evacuated by a vacuum pump and refilled with inert gas. The power to the individual element is increased with time to melt the polycrystalline charge completely and bring it into contact with the seed. A portion of the seed is also remelted to expose a fresh growth interface (Fig. 10.6a). Crystal growth is initiated by cooling the melt from the seed end. The temperature gradient at each and every point along the growth direction can be controlled very accurately due to the multiple zones (Fig. 10.6b). The sophisticated thermal controls also make gradient freezing systems more complex than typical Bridgman systems. Unlike simple resistance heater wires wound around tubes as in Bridgman-type systems, gradient freezing units have advanced heater designs. Some systems have water cooling tubes between the heater plates to ensure sharp and controllable temperature gradients along the length of the furnace.

For semiconductor crystal growth, oxygen in the melt must be eliminated completely. Hence crystal growth chambers are designed to be vacuum-tight as well as to withstand high internal gas pressures. After loading the crucible with charge, the growth chamber is evacuated to a high vacuum (1 mTorr or less pressure) and repeatedly flushed with an inert gas mixture such as argon/hydrogen or hydrogen/nitrogen to ensure the removal of moisture and oxygen from inside the chamber.

During the charge synthesis and growth, the chamber is filled with an inert gas and a pressure is maintained beyond the vapor pressure of the melt in the chamber.

10.4.3 Seed Generation for New Materials

For single-crystal growth of any material, a single-crystalline seed of specific orientation is necessary. For a new material under development, single-crystal seeds are not available. Single-crystal seeds can be generated by vertical Bridgman growth using specially tipped crucibles [10.39] as shown in Fig. 10.7. There are two ways this can be made possible. In the first scenario (Fig. 10.7a), a natural seed selection process can occur at the tip region of the crucible. A specific nucleus can grow faster than the others and outgrow the rest of the nuclei. However this process is completely random and cannot be expected to repeat in every experiment. Hence a more predictive way of selecting an individual seed orientation is via the necking process (similar to what is being done in the Czochralski crystal growth process). In this process (Fig. 10.7b), randomly nucleated grains are subjected to a filtering process at the necking point in the crucible so that only one orientation reaches the main body of the crucible and grows into a bulk ingot. However, the production of a single-crystal grain cannot always be guaranteed by either of these processes. Random secondary nuclei from the crucible walls, such as shown in Fig. 10.7b, are often seen. Hence liquid encapsulation with low-melting-point liquids or crucible coating, e.g., with carbon, is necessary to avoid the melt touching the crucible wall during growth. This process,

Fig. 10.7a–c Single-crystal seed generation processes: (a) by natural selection, (b) by necking, and (c) by necking and liquid encapsulation

depicted in Fig. 10.7c, is the most predictive way to ensure a single-crystal seed generation process. Due to the random nature of the initial seed orientation, the single-crystal seed is then oriented along a preferred crystallographic direction using the x-ray orientation method. The ingot is then mined to obtain a seed with a specific orientation for further crystal growth experiments. For a cylindrical seed, a diamond core drill could be used. For rectangular-shaped seeds, the ingot can be sliced using a blade or a wire saw.

10.4.4 The Seeding Process

The initial stage of the crystal growth experiments wherein a single-crystalline seed is contacted with the molten charge is crucial and requires adequate care and experience. High-quality single-crystal seeds are precious and used repeatedly for a large number of experiments. The seeds are smaller in diameter with respect to the final diameter of the grown crystals. For example, a typical seed diameter is 5 mm (with 5–6 cm in length), while the grown crystals could be 50–75 mm in diameter. The seed needs to be partially remelted (≈ 0.5 cm) to expose a fresh growth interface and then the crystal growth is started. Unlike in the Czochralski growth method, the seed–melt interface during Bridgman growth (in most cases) cannot be observed due to the opacity of the crucible, melt, and/or the growth chamber. Hence for precise remelting of the seed during crystal growth, one needs to conduct a priori thorough analysis of the thermal environment of the growth chamber. Translating the crucible into the hot zone even by 1 mm could sometimes remelt the entire length (and hence loss) of the seed. This is due to the heat transfer from the melt to the seed by conduction and convection in the hot melt. For Bridgman and gradient freezing types of crystal growth experiments, in order to ensure the exact seeding position in the furnace, prior experimentation needs to be done with dummy melts and seeds. Since the heat transfer between the furnace, crucible, melt, and growth chamber is quite complex, any optimization of the seeding position needs to be carried out using a specific set of crucible diameter, crucible holder design, crucible material (pyrolytic boron nitride (pBN), silica, graphite, alumina, etc.), melt depth, seed length, etc. If any of the above parameters is altered during the actual crystal growth experiment, the seeding position will change.

For the seeding position determination, two sets of experiments need to be carried out. In the first experiment, a polycrystalline charge (of the same material

to be grown) is melted into a crucible with the exact shape as is to be used in the final crystal growth experiment. The melt is then directionally solidified as in the real crystal growth experiment. The polycrystalline ingot, which is shaped like a crystal with a seed at the end (Fig. 10.3b), is removed from the crucible and then chemically etched to make the surface shiny (as described in Sect. 10.5.4). In the second experiment, this polycrystalline ingot is placed inside an identical crucible (as in the first experiment). The crucible is then slowly translated into the hot zone of the furnace to remelt the ingot to a desired point and then directionally solidified by translating the crucible back into the cold zone. After the experiment, one can easily observe the interface between the remelted and unmelted portions of the ingot. By repeating this process, one can identify the crucible location in the furnace that will provide the desired seed–melt interface. Since this process is rigorous, once the crucible location has been identified for proper seeding, it is advisable to maintain the same conditions during actual crystal growth experiments. Slight changes such as an increase or decrease in melt height or thickness of crucible wall could lead to a large variation in the seeding interface location. Hence in large-scale crystal production, the design of the entire crystal growth systems is properly analyzed and crystal growth conditions are kept unchanged.

10.4.5 Growth Rate Determination Methods

The crystal growth rate is an important factor that dictates the crystalline quality and microstructure of the grown crystals. For crystals grown from melt in crucibles using Bridgman or gradient freezing techniques, precise determination of growth rates requires considerable experimental effort. There are a few techniques that have been developed and used for determining the growth rate of crystals, as briefly discussed below [10.46–65]. The choice of technique is decided by the crystal growth temperature, and the optical, electrical, and thermal properties of the melt, crystal, and crucible material.

Depending on the crystal to be grown, a proper choice of crucible material is necessary based on its chemical reactivity with the melt. There may be more than one option for the crucible material for any specific melt. The final selection of the crucible material is made based on several other factors such as heat transfer and thermal configurations, use of melt encapsulations, the thermal expansion coefficient of the grown crystal, application of external fields during growth, etc. Hence,

based on the crucible material, a specific growth rate determination method is used. For example, crucible material such as silica (quartz) is optically transparent and hence the melt–crystal interface can be directly visualized during growth if a transparent furnace configuration is used. On the other hand crucibles made of pyrolytic boron nitride (pBN), alumina, graphite, etc. are opaque and hence indirect methods for melt–solid interface visualization are necessary. The thermal conductivity of the crucible material contributes to the heat transport from the hot zone to the cold zone of the furnace and thus has a significant effect on the melt–crystal interface shape and the growth rate of crystals. In the case of crystals grown under applied electric and magnetic fields, it is important to select a crucible material with appropriate electrical conductivity.

For crystals with low growth temperature (below 1000°C) that can be grown in a transparent crucible such as silica, the determination of growth rate is relatively straightforward. Since furnaces with optically transparent walls can be used for low growth temperatures, one can directly observe the melt and crystal inside the crucible. In these furnaces, a resistive heating coil is enclosed inside a transparent or semitransparent silica tube. Usually the furnace wall is coated with a thin film of reflective metal such as gold to reduce radiative heat losses. By in situ observation of the length of solidified melt with time (due to directional cooling), one can easily calculate the growth rate. This method has been used for determining the growth rate of optically transparent crystals as well as metal and semiconductor crystals [10.28, 46]. In the case of optically transparent material, the transparencies of the melt and the solid need to be different in order to observe a clear demarcation at the melt–crystal interface. For metallic or semiconductor crystals, typically the optical reflectivities of the melt and the solidified crystal are different, thus providing a clear delineation at the melt–crystal interface. This method cannot be used when the crystals need to be grown in an opaque crucible such as pBN or when a furnace with opaque insulation wall is used. Typically, for growth temperature exceeding 1000°C, the furnace wall is insulated with alumina or quartz wool and is opaque. In such scenarios, there are four methods for determining the growth rate, namely, melt quenching, Peltier interface demarcation (PD), periodic external field application, and real-time radiosopic x-ray/ γ -ray visualization.

In the traditional melt quenching method [10.47–49], the crystal growth experiment is terminated by rapid cooling of the melt after a certain period. When

the solidified ingot is sliced along the growth direction, one can easily observe two interfaces. The first interface is seen at the seeding point (at the first-to-freeze position on the seed crystal). The second interface is seen where the growth is terminated by rapid quenching. By measuring the distance between the two interface positions and the total growth duration, one can obtain the average growth rate. The sliced specimens generally requires metallographic preparation via coarse grinding and fine polishing (using abrasive powders or polishing slurries) followed by chemical etching (with a suitable etchant solution) to reveal the interface demarcation striations under Nomarski interference contrast microscopy. The quenching method is a universal technique that can be used for any material system irrespective of optical, electrical, and thermal properties. However it gives no information on the evolution of the solid–liquid interface position during growth. This is a major limitation since the crystal growth rate varies with time during the experiment as a result of varying heat flow through the melt and the crystal (due to changing axial temperature gradient in the melt and solid) as well as alloy segregation (as in the case of ternary and quaternary semiconductor alloys).

For crystals and melts with good electrical conductivity, the PD can be employed [10.50–56]. In a typical experiment, two electrical contacts are made: one at the top of the melt using an appropriate electrode material (that will not react with the melt) and one at the bottom of the seed crystal. In this method, thermoelectric effects induced by a current pulse passing through the melt and the directionally solidifying sample results in the creation of a rapid thermal perturbation at the solid–liquid interface. A series of perturbations result in concentration variations which, after being revealed by postgrowth metallography, delineate the instantaneous interface shape at successive times during growth and enable one to follow the time evolution of the solid–liquid interface. This method has been successfully used for metallic alloys and semiconductor materials. Since electric current needs to flow through the melt and the crystal, it is difficult to implement the PD process in materials with low electrical conductivity.

An elegant way of determining the crystal growth rate is by the application of periodic external fields during growth [10.57–60] such as by rotating magnetic fields or alternating electric fields. In the absence of an applied magnetic field, growth striations appear in the crystals due to natural convection. If the melt convection is suppressed by applied fields, the striations are not seen. By periodically switching on and off the ex-

ternal magnetic fields, one can create or suppress the growth striations. Postgrowth analysis of the specimens by selective chemical etching reveals the regions with striations and striation-free zones. By correlating the length of the individual zones with the field application durations, one can easily determine the growth rate. This technique cannot be used if the growth conditions have been optimized to obtain striation-free crystals without external fields. The application of alternating electric field has been found to alter the microstructure of the crystalline material. Hence, by switching on and off the field, one will obtain regions with different microstructures. The growth rate can be determined easily by postgrowth analysis of the cross-sectional view of the specimen after metallography.

A technique which is very attractive for real-time interface shape monitoring as well as growth rate determination is the use of x-rays and gamma-rays [10.61–

65]. This technique is based on the differential transmission of the x-rays or gamma-rays through the solid and the liquid phases. This difference in transmittance could be due to: (a) density difference between the liquid and solid phases, (b) crystalline structure (long- or short-range ordering), (c) dopant (impurity) distribution in the two phases (due to impurity segregation), etc. In the case of dopant distribution, the absorption coefficient of the radiation increases with increasing impurity concentration. This results in image contrast between the solid and liquid phases due to differences in the amount of radiation absorbed (or transmitted) through the individual regions (solid or liquid). One advantage of the radiosopic system is the ability to melt a single sample, solidify it, remelt it, and then change experimental parameters for a different case study. In this manner one can produce a large range of data in a single experiment.

10.5 Overview of III–V Binary Crystal Growth Technologies

Since the focus of this chapter is on ternary crystal growth, the topic of binary III–V bulk crystal growth (excluding the nitrides) using Bridgman or gradient freezing types of processes will be briefly reviewed. This is done to highlight the fundamental differences between the growth conditions of binary versus ternary compounds and the additional advances necessary for ternary crystal growth.

10.5.1 Phase Equilibria for Binary Compounds

Binary compounds such as GaAs, InP, GaSb, etc. are synthesized by mixing the individual elements such as gallium, indium, arsenic, phosphorus, antimony, etc. beyond the melting points of the compounds. Table 10.3 lists the melting points of As-, P-, and Sb-based III–V compounds [10.66, 67]. For compound synthesis, one needs to review the thermodynamic phase diagram. Figure 10.8 shows a schematic phase diagram typical of any III–V binary compound (except the nitrides). This schematic diagram depicting GaAs is not the actual phase diagram, but rather a sketch to explain the important features of the phase formation during compound synthesis and crystal growth. Due to their very high melting temperatures and extreme vapor pressures (exceeding 40 000 atm), GaN, AlN, and InN cannot be grown from stoichiometric melts by Czochralski or Bridgman-type techniques [10.68].

The phase diagrams of various III–V binary compounds can be found in the literature [10.66, 67]. According to the phase diagram shown in Fig. 10.8, the most stable phase is the one where the ratio of group III to group V mole fraction is close to 1 [10.1, 69]. Due to the narrow stability region, the solidus is shown by a vertical line at a composition of 50 at. % (the stoichiometric composition). As shown in Fig. 10.8, the

Table 10.3 Melting points of elements and III–V binary compounds

Material	Melting point (°C)

InAs	942
AlSb	1065
GaSb	712
InSb	527

Fig. 10.8 Schematic binary phase diagram of III–V semiconductor (depicting GaAs)

stoichiometric melting point for GaAs is 1238 °C. The congruent melting point is typically slightly shifted from the stoichiometric composition. In the case of GaAs, the congruent melting point is on the arsenic-rich side of the phase diagram [10.69], and in the case of GaSb it is on the Ga-rich side [10.16]. The slight deviation from stoichiometry leads to point defects (native defects such as vacancies, interstitials, and antisites of group III and V elements) in the crystals, which affect the electrical and optical properties of the grown crystals [10.1, 16, 69].

Referring to Fig. 10.8, above the liquid curve (melting temperature), a uniform liquid region (melt) exists. Depending on the ratio of gallium to arsenic, the melting temperature varies. Irrespective of the growth temperature, the composition of the solid (solidus) that precipitate out of the liquid is always the stoichiometric compound GaAs. On the gallium-rich side, the melting point can be as low as 29 °C, which is the melting point of liquid gallium. However the solubility of arsenic in gallium decreases sharply as the temperature decreases. As the melt temperature is decreased, GaAs precipitates out first and then the excess gallium or arsenic solidifies. This phase formation property is used advantageously to grow binary compounds from group III- or group V-rich solutions at temperatures lower than the stoichiometric melting point. On both sides of the stoichiometric melting point, equilibrium regions with solid GaAs and Ga-rich or As-rich solution exist. Below a specific temperature, regions shown as solid GaAs

plus solid arsenic or solid gallium exist, depending on the excess element in the starting melt.

Due to the high vapor pressure of the group V elements, III–V compounds generally dissociate above the melting points. However, the dissociation rate depends on the partial vapor pressures. Antimony is the least volatile species amongst the group V elements. The partial vapor pressure of antimony at the melting point of GaSb (712 °C) is 3×10^{-6} Torr. Typically, during 10 h of GaSb growth, 10^{-3} moles of Sb would be lost from the melt [10.16]. The rate of antimony loss from AlSb melt at 1300 °C is ≈ 0.25 g/h [10.70]. The next most volatile species is arsenic. The vapor pressure of arsenic in equilibrium with GaAs melt at its melting point (1238 °C) is 1 atm. The phosphorus vapor pressure is the highest. At the melting point of InP (1062 °C), the vapor pressure in equilibrium with InP melt is ≈ 27 atmosphere. For comparison, the partial pressure of Ga, In, and Al is less than 10^{-6} Torr at the melting points of various compounds. To avoid evaporation of the group V element from the melt, pressure above the partial vapor pressure needs to be applied to the melt. This requires specially made high-pressure stainless-steel vessels, inside which the furnace is assembled.

10.5.2 Binary Compound Synthesis

In this section, we describe Bridgman or gradient freezing types of process that are being used for synthesizing the binary compounds [10.1, 16, 39–44, 66, 71–73, and references therein]. In this process, the starting ma-

Fig. 10.9 InSb polycrystalline charge synthesis in a sealed crucible using a rocking furnace

terials (charge) consisting of equal mole fractions of the group III and group V elements are weighed and placed into a crucible. Depending on the compound to be synthesized, the placement of the elemental charges inside the crucible could be different, as described below. The crucible with the charge is then heated beyond the melting point of the binary compound and the compound synthesized in liquid form. Thereafter the melt is directionally solidified and slowly cooled to room temperature. Amongst the group V el-

ements, arsenic and phosphorus tend to be extremely volatile. Hence an overpressure of the group V element is necessary during the synthesis. Different configurations are used for compound synthesis and crystal growth of InP, GaAs, GaSb, AlSb, etc. Schematic diagrams of the experimental setups used for synthesizing arsenide-, phosphide-, and antimonide-based compounds are shown in Figs. 10.9–10.15. In this section, we summarize the general schemes for the compound synthesis.

Antimonide-Based Compounds

GaSb and InSb are the easiest compounds from the point of view of synthesis. The vapor pressure of antimony is very low at the melting points of the compounds. Hence both InSb and GaSb can be synthesized by simply melting and mixing the two constituents elements at a temperature beyond the melting point of the binary. The synthesis could be carried out either in a sealed (Fig. 10.9) or open crucible (Fig. 10.10). Inside the sealed crucibles, the vacuum level is typically 10^{-6} Torr or less. For open crucibles, inert-gas ambient is necessary. For synthesis of InSb, indium and antimony are mixed in equal mole fraction (1 : 1). Hence 114.82 g of indium and 121.75 g of antimony are necessary. The two elements are then heated to at least 20°C more than the melting point of InSb (527°C) and thoroughly mixed for several hours (10–12 h). Melt mixing could be implemented in sealed crucibles by rocked the crucible along with the furnace like a see-saw as shown in Fig. 10.9. At the end of the homogenization process, the furnace is held horizontal or vertical and the crucible is translated out of the furnace at a rate of 3–5 mm/h to directionally solidify the melt.

Figure 10.10a shows a schematic of GaSb synthesis in an open crucible configuration. The crucible is packed with antimony, gallium, and alkali halide salt (for melt encapsulation). The entire charge is heated to beyond the melting point of GaSb (712°C) and the compound is synthesized by mixing the melt. For melt homogenization, the crucible can be rotated with a stationary stirrer in the melt, as shown in Fig. 10.10a. Another efficient approach for melt mixing is by using a baffle or a plate with holes made out of the same material as the crucible (Fig. 10.10b). The baffle or mixing plate can be moved back and forth from the top to the bottom of the melt, creating turbulent flow through the narrow regions across the moving object. This leads to very rapid mixing. Hence large melts can be thoroughly mixed in minutes as opposed to hours (as is necessary with crucible rotation or rock-

Fig. 10.10a,b GaSb polycrystalline charge synthesis in an open crucible by (a) using a stirrer and (b) using a quartz baffle for melt mixing

ing). After the melt has been completely homogenized, it is directionally solidified by translating the crucible at a rate of 3–5 mm/h in a furnace with a temperature gradient of 10–15 °C/cm until the entire liquid turns solid. After that the furnace is slowly cooled to room temperature at a rate of 15–20 °C/h. The presence of alkali halide salt encapsulation on the top of the melt helps avoid volatilization of antimony from the melt surface. As discussed earlier, the usage of liquid encapsulation during single-crystal growth is crucial to avoid melts touching the crucible walls and polycrystalline growth. The synthesis process for InSb and GaSb is exactly the same except for the synthesis temperature.

For AlSb, the problem is the sticking of the aluminum with crucible materials such as silica, pBN or graphite. Recently, a new process for synthesis and growth of AlSb in silica crucibles using alkali halide

salts as encapsulants has been demonstrated [10.71]. The adhesion of AlSb melt to silica crucible could be eliminated by employing a LiCl/KCl encapsulation [10.72] in conjunction with excess antimony in the melt. This process is shown schematically in Fig. 10.11a–c. The placement of the elements in the crucible (as shown in Fig. 10.11a) is crucial for successful synthesis of the compound without rupturing the crucible during the experiment. Care should be taken to avoid the elemental aluminum coming into contact with the silica crucible. The LiCl/KCl (58 : 42 mol %) eutectic salt mixture first melts and covers the crucible walls. Then the antimony melts and encapsulates the aluminum until it melts. The temperature of the melt is then increased to beyond the melting point of AlSb (1065 °C). The rest of the synthesis steps are similar to those for GaSb shown in Fig. 10.10.

Fig. 10.11a–c Materials stacking scheme for AlSb synthesis in a quartz crucible

Fig. 10.12 GaAs synthesis inside sealed tube using a horizontal Bridgman configuration

Arsenide-Based Compounds

There are three general synthesis procedures for arsenic-based compounds. The configurations are shown in Figs. 10.12–10.14. Here we provide the specific examples of GaAs synthesis.

For GaAs, the synthesis is done under excess pressure of As. In the horizontal Bridgman method shown in Fig. 10.12, a sealed quartz tube containing 7 N pure gallium at one end separated and 6 N pure arsenic at the

other end is used. The quartz tube is placed in a two-zone furnace. The arsenic is kept between 600–620 °C (which results in ≈ 1 atm of arsenic vapor pressure) in the lower-temperature zone. The quartz boat containing the gallium is kept in the higher-temperature zone of the furnace above the melting point of GaAs (1238 °C). The arsenic vapor reacts with gallium to form the GaAs melt. A quartz baffle with narrow constrictions (silica baffle) between the two zones controls the transport of the arsenic. After the melt is homogenized for 12–24 h, the melt is directionally solidified by translating the crucible in a temperature gradient (10–20 °C/cm) at a rate of 1–3 mm/h. After the entire melt solidifies, the ingot is cooled slowly to room temperature over a period of 48 h.

Another method for synthesizing GaAs is the injection method (Fig. 10.13). In this method, the group V volatile element such as arsenic is contained in a quartz ampoule and heated to form vapors. The vapors are transported into the B₂O₃-covered molten gallium to form the compound (GaAs). The melt is maintained at a temperature higher than the melting point of GaAs. The pressure on the top of the melt must be maintained in the range 1–2 MPa (≈ 10 –20 atm). After the synthesis, the charge is directionally solidified and slowly cooled to room temperature. Since B₂O₃ reacts with quartz and crucible ruptures during cooling, pyrolytic boron nitride (pBN) crucibles are necessary for this process.

Direct synthesis of GaAs can be implemented by using the configuration shown in Fig. 10.14. The arsenic and gallium are packed together as shown in the figure with boric oxide as an encapsulant. The chamber in the pressure must be maintained to around 60 atm during the synthesis using nitrogen or argon. The synthesis of GaAs occurs around 700 °C by an exothermic reaction. After the compound is formed, the temperature is increased above the melting point of GaAs (1238 °C) and the pressure of the chamber can be reduced to 5–10 atm. The melt is then directionally solidified as in the previous cases.

Phosphide-Based Compounds

Phosphide-based materials such as InP and GaP have much higher vapor pressures than arsenide-based compounds. Hence specific modifications in configurations are necessary for the synthesis and growth of phosphide-based compounds. A stainless-steel-lined pressure vessel designed for 150–170 atm and continuous operation at 60–70 atm is necessary for InP growth. The direct synthesis method, which is the preferred syn-

Fig. 10.13 GaAs and InP synthesis using a As and P injection method inside a high-pressure chamber

Fig. 10.14 Direct synthesis of GaAs in an open crucible inside a high-pressure chamber

Fig. 10.15 InP synthesis inside a sealed tube using a horizontal Bridgman configuration with multizone heaters (RF heater refers to radio frequency heater coil)

thesis method for GaAs, is not possible for InP. Special handling procedures for phosphorus are necessary due to significant risk of ignition.

Two common InP synthesis techniques are the horizontal Bridgman (or gradient freezing) and the injection methods, as shown in Figs. 10.12 and 10.13. In the horizontal Bridgman process with a two-zone furnace (Fig. 10.12), indium is kept in a boat at one end and red phosphorus at the other end, and the silica tube sealed under 10^{-6} Torr. The sealed quartz crucible is kept inside a stainless-steel pressure vessel with preferably 45–50 atm of inert gas overpressure to avoid rupturing of the crucible. The red phosphorus is slowly heated to around 550°C to maintain a phosphorus pressure of 27 atm. The indium boat is maintained at 1075–1080°C. The phosphorus transports to the indium boat to form InP. After the homogenization of the melt, which could take 16–24 h, the melt is directionally solidified at a cooling rate of 0.5°C/h until the entire melt solidifies and the solid reaches around 1000°C. The crystal is then cooled to room temperature over a period of 30–40 h. Another common horizontal Bridgman-type configuration used for InP synthesis is shown in Fig. 10.15. The three-zone temperature profile resembles a zone-refining process and makes it easy to control the phosphorus vapor pressure on the melt and to avoid the supercooling effects seen in InP.

For the injection method shown in Fig. 10.13, the red phosphorus reservoir is maintained around 550°C and the indium is heated to 1080°C for the compound formation. The inert gas pressure in the chamber is maintained around 45–50 atm. The phosphorus vapors diffuse through the boric oxide to form InP. The melt is then homogenized and directionally solidified.

10.5.3 Single-Crystal Growth Processes

During the growth of binary compounds from melt, the macroscopic composition of the melt and the growing crystal remains constant (segregation coefficient equal to unity). Hence there is no need for solute replenishment processes (unlike in ternary crystal growth). Single-crystal growth is carried out by using a presynthesized polycrystalline charge and a seed. In addition, melt encapsulation is necessary for two reasons: (a) to avoid the escape of volatile species from the melt, and (b) to avoid contact between semiconductor melt and crucible walls during growth so that secondary nuclei, which lead to polycrystalline grains, do not originate. Details of crystal growth configurations and conditions can be found in the literature [10.1, 16, 40–44, 66, 71, 73, and references therein]. In this section, we present the schematics of the growth setups and summarize the growth conditions.

Fig. 10.16 Single-crystal growth of GaAs or InP inside a sealed tube using the vertical gradient freeze (VGF) method

Two typical VGF growth setups used for GaAs and InP are shown schematically in Figs. 10.16 and 10.17. In the sealed tube configuration (Fig. 10.16), a reservoir of a small amount of As or P is kept at a lower

temperature (the same as that used during synthesis) to maintain an adequate vapor pressure over the melt surface. In the open tube configuration (Fig. 10.17), the entire melt is pressured with an inert gas at a level of 10–20 atm for GaAs and 45–50 atm for InP growth. pBN crucibles along with ultralow-water-content boric oxide (B_2O_3) encapsulation is used. The boric oxide melts at 450 °C and has a low viscosity at the growth temperatures of GaAs and InP. The typical furnace temperature gradient is in the range of 5–10 °C/cm and the crystal growth rate is in the range of 0.5–2 mm/h. Growth of low-dislocation-density large-diameter (typically 100–150 mm) GaAs and InP has been demonstrated using the VGF technique. Semi-insulating GaAs crystals with a diameter of 200 mm are being produced today by VGF.

For the growth of GaSb and InSb, B_2O_3 encapsulation is not suitable since it is very viscous at low temperatures [10.73]. Instead of B_2O_3 , alkali halide eutectic salts such as LiCl/KCl (58 : 42 mol %) and NaCl/KCl (50 : 50 mol %) with low melting temperatures (between 350 and 600 °C) and significantly lower viscosity are used. These alkali halide salts do not react with the antimonide-based compounds and have no effect on the electrical and optical properties of the grown crystals [10.72]. Silica (quartz) crucibles are commonly

Fig. 10.17 Single-crystal growth of GaAs or InP in an open crucible using the vertical gradient freeze (VGF) method

used for GaSb and InSb growth. It should be noted that melt encapsulation for GaSb or InSb growth is not an absolute necessity. The vapor pressure of Sb is significantly lower compared with that of P or As. Nevertheless, alkali halide salt encapsulation does help in reducing the probability of polycrystalline growth from the crucible walls. Typically, thick oxide layers are present on GaSb and InSb polycrystalline surfaces (even after chemical etching). When the polycrystalline charge is melted, an oxide scum develops on the surface of the liquid. The scum in contact with the crucible walls enhances the sticking of the melt to the crucible and hence polycrystalline grains are formed. The salts help in dissolving the oxide scum and lead to a cleaner melt surface and avoid sticking of the melt with the crucible walls. The growth setup for GaSb and InSb is much simpler since there is no need for a high-pressure vessel. Typical vertical Bridgman or VGF can be used for single-crystal growth of low-dislocation-density GaSb and InSb. The typical furnace temperature gradient used for 50 mm diameter crystals is in the range of 5–15 °C/cm and the crystal growth rate is in the range of 1–3 mm/h.

10.5.4 Cleaning Procedures for Growth Chamber, Crucible, and Charge

Due to the high-purity nature of the semiconductor materials, the growth chambers, crucibles, and charge require special cleaning procedures. The growth chambers need to be cleaned prior to every experiment. Stainless-steel chamber surfaces must be scrubbed and cleaned to remove deposits of elemental and compounded species such as arsenic, antimony, GaAs, etc. from previous experiments. Proper safety masks, handling, and disposal procedures must be followed. After scrubbing, the chamber surfaces could be rinsed and wiped with an organic solvent such as methanol. If silica tubing is used in the growth chamber, they need to be chemically cleaned following the same procedures as for the crucibles as described below. All graphite parts such as the crucible holder must be cleaned with organic solvents (successively in xylene, acetone, and methanol) and then baked at high temperature (≈ 1200 °C) under high vacuum (less than 1 mTorr pressure) or under a flowing argon/hydrogen gas mixture.

Two most common crucible materials for III–V semiconductors are high-purity silica (quartz) and py-

rolytic boron nitride (pBN). High-purity, low-porosity graphite is also a suitable material. However due to difficulty in handling graphite, it is not used for bulk crystal growth. Prior to crystal growth, the silica and pBN crucibles need to be degreased in warm xylene followed by acetone and methanol. Depending on the residue material left behind from the previous experiment, such as GaAs or GaSb, the crucibles are chemically treated in a suitable chemical etchant solution to remove the residues. Typical etchants consist of acids such as nitric acid (HNO_3), hydrofluoric acid (HF) and glacial acetic acid (CH_3COOH) mixed in various volume ratios [10.74]. The crucibles are finally rinsed in high-purity deionized (DI) water and methanol, and dried with nitrogen gas.

For polycrystalline charge synthesis, the elemental constituents are accurately weighed according to the melt composition required. Elements with purity level of 6 N (99.9999%) or 7 N (99.99999%) are commercially available and used these days. The elements are available in various forms; for example, gallium comes in squeeze bottles or in the form of solidified rods; indium comes in tear drops or bar forms; while antimony, phosphorus, and arsenic come in small pellets. If the elements are opened from packed containers, they can be used the experiments without any cleaning. However, oftentimes the elemental charge possesses a thick oxide layer on the surface. Hence it is necessary to clean the charge before synthesizing compounds. Common cleaning procedures involve acid rinsing the oxide layer from the surface of the elements followed by cleaning in high-purity water, methanol rinsing, and nitrogen drying. Typical etchants for elemental cleaning includes hydrochloric (HCl), nitric (HNO_3), and hydrofluoric (HF) acids [10.66]. When polycrystalline compounded materials such as GaAs, GaSb, InSb, etc. are used for single-crystal growth experiments, they are etched in a variety of acids that act as etchants for the specific compound [10.74]. One such etchant that is widely used is a mixture of HNO_3 , CH_3COOH , and HF in the volume ratio 5 : 3 : 3, respectively. The polycrystalline charges are finally washed in high-purity water, rinsed with methanol, and dried by blowing nitrogen gas. Since there are numerous options for chemicals used in cleaning elemental and compound charges, no specific recommendations are made here. Every crystal grower adopts specific cleaning procedures based on the ease of handling certain chemicals, and experience.

10.6 Phase Equilibria for Ternary Compounds

There are three types of phase diagrams that can be used for the growth of ternary compounds, namely pseudobinary, ternary, and quaternary phase diagrams [10.17,29,30,66,75–77]. In this section, we will discuss the methods to use these phase diagram for determining melt or solution composition and the growth temperature for growing a crystal of specific composition.

10.6.1 Pseudobinary Phase Diagram

The most common phase diagrams used for melt growth of ternary crystals are the pseudobinary plots, as shown in Fig. 10.18 (depicting the GaInSb system [10.77]). These are known as pseudobinary diagrams because a ternary crystal such as $\text{Ga}_{0.6}\text{In}_{0.4}\text{Sb}$ can be thought of as a mixture of two binary compounds, namely, 60 mol % of GaSb and 40 mol % of InSb. In this diagram there are two curves: liquidus and solidus. The melting points of the two constituent binaries are shown on the y-axis at the two ends points. The melting points for pure InSb and pure GaSb are 527 and 712 °C, respectively. Any point on the liquidus curve represents the temperature above which the ternary of a specific composition is completely liquid. For example, $\text{Ga}_{0.6}\text{In}_{0.4}\text{Sb}$ or a mixture of 60 mol % GaSb and 40 mol % InSb will be completely liquid above 660 °C. When the individual binaries are mixed together, the InSb first melts at 525 °C and starts dissolving GaSb. As the temperature is increased, the amount of GaSb dissolved increases, resulting in a melt composition with increasing GaSb mole fraction or decreasing InSb mole

fraction. The ternary compounds can also be prepared by mixing individual elements such as Ga, In, Sb, etc. For example, $\text{Ga}_{0.6}\text{In}_{0.4}\text{Sb}$ can be prepared by mixing 60 mol % Ga, 40 mol % In, and 100 mol % Sb. The liquidus and solidus temperatures are independent of the preparation methodologies.

The solidus represents the temperature below which a ternary of specific composition is completely solid. For example, $\text{Ga}_{0.6}\text{In}_{0.4}\text{Sb}$ will be completely solid below 570 °C. Between the liquidus temperature and the solidus temperature for a specific ternary composition, there exist a two-phase region, as shown in Fig. 10.18, where a portion of the material is in liquid state and the rest is in solid state. In pseudobinary phase diagrams, there exist a single growth temperature and a single melt composition for any solid composition. For example, for growing $\text{Ga}_{0.8}\text{In}_{0.2}\text{Sb}$ crystals, the melt composition must be $\text{Ga}_{0.30}\text{In}_{0.70}\text{Sb}$ and the growth temperature is 605 °C. A horizontal line connecting a point in the liquidus and solidus is known as a tie-line. This is different than the ternary and quaternary phase diagrams (to be discussed next), where a specific solid composition can be obtained at numerous liquid compositions and growth temperatures.

10.6.2 Ternary Phase Diagram

Using the pseudobinary phase diagrams discussed above, the growth temperature of any ternary crystal is restricted to lie the melting points of the two constituent binaries. Growth of crystals from solution at lower temperatures has many advantages such as reduced native defects and lower dislocation densities that result in superior materials properties. Ternary phase diagrams can be used to grow crystals at low temperatures. Figure 10.19 shows a typical ternary phase diagram for the GaInSb system. This diagram is a schematic drawn to demonstrate the features of the ternary phase diagrams. The three vertices on the equilateral triangle represent the three constituent elements comprising the ternary compound. For GaInSb growth, the constituents are Ga, In, and Sb. The melting point of Ga, In, and Sb are 29, 156, and 630 °C, respectively. The low melting point of one or two constituent elements helps to decrease the growth temperature significantly. Each point within the triangular area represents a specific solution (liquid) composition (Ga : In : Sb in mol %). The lines drawn parallel to each face are used to determine the solution composition. For example, as one traverses the

Fig. 10.18 Schematic pseudobinary phase diagram of a III–V ternary compound (depicting GaInSb)

space from the Sb vertex of the triangle downwards, the Sb content changes from 100 mol % to 0 mol % at the opposite face (which connects In and Ga). The same methodology can be applied for calculating the In and Ga compositions. The compositions of the liquid at the four circular dots in Fig. 10.19 have been calculated by drawing three straight lines parallel to each triangle axis, intersecting at the circular dot. The compositions for In, Ga, and Sb are then estimated by measuring the distance between the point of interest and each vertex of the triangle.

Referring to Fig. 10.19, the liquidus are shown by solid lines and the solidus are shown by dashed lines. Each liquidus curve corresponds to a specific solution (liquid) temperature. For example, the two liquidus shown correspond to 575 and 625 °C. Each solidus curve corresponds to a specific ternary solid composition. For example, the two solidus curves shown correspond to gallium mole fractions of 0.7 and 0.8 in the crystal. For the growth of crystal of any desired composition from a solution, one needs to find a specific solution composition and the growth temperature. This is done by finding a point in the ternary phase plane where the solidus and liquidus curves cross each other such as the points (In,Ga,Sb: 50,15,35 and 35,35,32) in Fig. 10.19. Hence, to grow a crystal of $\text{Ga}_{0.7}\text{In}_{0.3}\text{Sb}$ at 575 °C, the solution composition should be (In : Ga : Sb = 50 : 15 : 35 by mol %). It should be pointed out that there is more than one option for the growth temperature and liquid composition for the same crystal composition. It is also interesting to note that, even though the liquid compositions are completely nonstoichiometric ($\text{Ga}_x\text{In}_y\text{Sb}_z$; $0 < x, y, z < 1$), the grown solids are stoichiometric, of the form $\text{Ga}_{1-x}\text{In}_x\text{Sb}$ ($0 < x < 1$).

10.6.3 Quaternary Phase Diagram

Recently, it has been demonstrated that quaternary melts can be used to grow ternary crystals [10.29, 30, 78]. The growth of $\text{Ga}_{1-x}\text{In}_x\text{As}$ from stoichiometric $\text{Ga}_{1-x}\text{In}_x\text{As}_y\text{Sb}_{1-y}$ melt has been clearly demonstrated [10.29, 78]. Other III–V ternary systems such as GaInP, GaAsSb, and AlGaP, can also be grown from GaInPSb, GaInAsSb, and AlGaPSb melts, respectively [10.30]. The use of a quaternary melt enables the growth of ternary crystals at lower temperature compared with that possible using pseudobinary phase diagrams. Figure 10.20 shows a schematic phase diagram of the Ga-In-As-Sb system at 950 °C. The four constituent binaries for Ga-In-As-Sb are GaAs,

Fig. 10.19 Schematic ternary phase diagram of a III–V ternary compound (depicting GaInSb)

InAs, InSb, and GaSb. The quaternary phase diagram shows a liquidus curve and a solidus curve connected with tie-lines across the two-phase regions. The melt composition for growing a specific solid composition can be obtained by selecting a specific tie-line in the phase diagram. Like in the case of the ternary phase diagrams, depending on the growth temperature, the liquid composition for growing a particular solid composition varies. For example, the liquid composition of Ga-In-As-Sb to grow $\text{Ga}_{0.2}\text{In}_{0.8}\text{As}$ at 950 °C and 1000 °C are different. Using MTDATA, the National Physical Laboratory (NPL, UK) database for metallurgical thermochemistry, phase diagrams for the $\text{In}_x\text{Ga}_{1-x}\text{As}_y\text{Sb}_{1-y}$ system have been calculated for a wide temperature range [10.29, 30]. For temperatures below the melting point of InAs (942 °C),

Fig. 10.20 Schematic quaternary phase diagram for III–V ternary compound growth (depicting GaInAs) from quaternary melt

$\text{Ga}_{1-x}\text{In}_x\text{As}$ (with residual Sb) and $\text{Ga}_{1-x}\text{In}_x\text{As}_y\text{Sb}_{1-y}$ solids can be grown from the Ga-In-As-Sb quaternary melts. Above the InAs melting point, only ternary $\text{Ga}_{1-x}\text{In}_x\text{As}$ is formed from the $\text{Ga}_{1-x}\text{In}_x\text{As}_y\text{Sb}_{1-y}$ melt. Figure 10.20 clearly shows that a wide range of GaInAs compositions could be grown using Ga-In-As-Sb melt at temperatures as low as 950 °C. Due to the fact that the first-to-freeze solid is ternary, the melt composition changes to a nonstoichiometric Ga-In-As-Sb from a stoichiometric starting melt (excess Sb in the solution). Hence replenishment of depleted species is necessary to keep the melt stoichiometric at all times.

The growth of a ternary from quaternary melt occurs at higher temperatures compared with growth from ternary solutions. Nevertheless, there are several tech-

nical advantages in using the quaternary melt. Since the quaternary melts can be prepared from presynthesized binary compounds, it enables the usage of liquid encapsulations during the growth. The metal-rich ternary solutions (such as Ga, In, Al) tend to stick to the crucible, making them difficult to mix and posing problems during Bridgman growth. Also the solubility of compounds in ternary solutions is significantly lower than in quaternary melts. This impacts the crystal growth rates. Another advantage of using the quaternary melts is seeding during a typical Bridgman growth. Due to the numerous technical benefits of the quaternary melts for ternary growth at low temperatures, this method will receive significant interest in the future, especially for crystals with high growth temperature (such as phosphides and arsenides).

10.7 Alloy Segregation in Ternary Semiconductors

All three types of phase diagrams discussed above for the growth of ternary crystals exhibit a common phenomenon. The solid composition precipitating out of the melt or solution is different from the liquid composition. This leads to alloy segregation, as discussed here. For the sake of simplicity, we will only discuss the pseudobinary phase diagrams since in this case one only needs to track the changes in concentration of one of the binary constituents. For example, during the growth of $\text{Ga}_{1-x}\text{In}_x\text{Sb}$, either the change in InSb concentration or GaSb concentration needs to be analyzed. The InSb and GaSb concentrations are complementary to each other. On the other hand, while using ternary or quaternary phase diagrams, the individual elemental concentrations such as Ga, In, As, Sb, etc. need to be analyzed since the concentration of each elemental species varies independently during the growth.

As shown in Fig. 10.18, pseudobinary phase diagrams exhibit a separation between the solidus and liquidus curves. Starting from a melt of alloy composition (A), when the liquid is cooled below the liquidus temperature T_A , the composition of the solid precipitating out of the liquid will have a composition corresponding to the point on the solidus (B) at the temperature T_A . Since the solid composition (B) is different than the liquid composition (A), the melt composition will change as soon as the solid starts precipitating out of the liquid. During crystal growth, the rejected species accumulate in front of the interface and spread into the liquid phase by diffusion and mixing induced by convection. From the phase diagram, it is clear that the

rejected species is the lower-melting binary constituent. For example, during the growth of $\text{Ga}_{1-x}\text{In}_x\text{Sb}$, the precipitating solid is rich in GaSb compared with the liquid. Hence the excess InSb is rejected into the melt at the solidification interface and the melt composition changes to a point indicated by A_1 in Fig. 10.18. The next precipitation event occurs at a lower temperature shown by T_{A_1} with the precipitating solid of composition B_1 . This continues and hence, during normal directional solidification process from melt as in Bridgman or Czochralski growth, the melt composition continuously changes with time, as in turn does the composition of the solidifying crystal.

The changing alloy composition in the solid can be theoretically analyzed using the fundamental equilibrium distribution (partition) coefficient or chemical segregation coefficient, k_0 . This can be derived from the equilibrium phase diagram by the ratio of the solidus (C_s) and liquidus concentration (C_l) of a species at a given temperature (Fig. 10.18) as follows

$$k_0 = \frac{C_s}{C_l} \quad (10.3)$$

In general, segregation depends on the growth rate and hence is described by an effective distribution coefficient, k_{eff} . If the melt is mixed continuously during a directional solidification crystal growth experiment, the alloy concentration in the solid is given by the well-known equation [10.79–82]

$$C_s = k_{\text{eff}} C_0 (1 - g)^{k_{\text{eff}} - 1} \quad (10.4)$$

where g is the fraction of melt solidified and C_0 the initial concentration of the melt (at the beginning of the growth). In this equation k_{eff} does not vary with alloy concentration, an assumption which is invalid for ternary crystal growth, as discussed below.

In a typical crystal growth experiment, the rejected species at the solid–liquid interface takes a finite time to diffuse back into the melt, giving rise to a completely homogeneous melt. The mixing rate of the rejected species with the rest of the melt can be enhanced by increasing the temperature gradient across the melt–solid interface, decreasing the cooling rate of the melt (decreasing the crystal growth rate), and by using forced convection. There are limitations with each of these processes. Large temperature gradients lead to temperature fluctuations, almost inevitably producing striations. Slow cooling increases the duration for crystal growth, which is undesirable for a variety of reasons (increase in cost, reduced equipment lifetime, unexpected long-term instability in furnace power, enhanced degradation of grown crystals due to volatilization of elements from the surface of the crystals and melt, etc.). Forced mixing has its own limitations such as complicated fluid patterns and associated temperature and solutal fluctuations. Thus, under normal conditions, the growth process is dominated by a stagnant (or diffusion) boundary layer of thickness δ , beyond which stirring in the bulk liquid ensures a uniform bulk concentration. Within the diffusion boundary layer, the composition of the rejected species changes continuously starting from the crystal surface to the end of the boundary layer [10.81]. Burton, Prim, and Slichter (BPS) derived the following equation to correlate the boundary-layer thickness with the effective segregation coefficient [10.81]

$$k_{\text{eff}} = \frac{k_0}{k_0 + (1 - k_0) \exp(-\Delta)}, \quad (10.5)$$

$$\Delta = R\delta/D,$$

where k_0 is the equilibrium segregation coefficient as estimated from the equilibrium phase diagram, D is the diffusion coefficient of the rejected species in the melt, R is the crystal growth rate, and δ is the thickness of the boundary layer. For crystal grown with forced convection, the boundary-layer thickness δ is given by

$$\delta = 1.6D^{\frac{1}{3}}\nu^{\frac{1}{6}}\Omega^{-\frac{1}{2}}, \quad (10.6)$$

where ν is the kinematic viscosity of the melt, Ω is the rotational rate of the crystal or seed (in the case of Czochralski growth), and D is the diffusion coefficient.

As can be seen from the above equation, when Δ approaches zero, k_{eff} equals k_0 . In the above equation, the

diffusion coefficient D is a fundamental material property and dependent on the alloy composition as well as the temperature. For example, the diffusion coefficient of InSb in GaInSb melt at 550 °C is different from that at 600 °C. Similarly, the diffusion coefficient of InSb in a Ga melt at 550 °C is different from that in GaInSb melt at the same temperature. The diffusion boundary-layer thickness can be altered by the hydrodynamic mixing in the melt as a result of natural and forced convection as well as diffusion. In the analysis shown above, k_0 is assumed to be constant with time. However during ternary crystal growth, the liquid concentration moves along the liquidus. For each corresponding liquidus and solidus points, the segregation coefficient is different. Hence the k_0 needs to be varied for analyzing the solid concentration along the crystal growth direction. Figure 10.21 shows the theoretically calculated gallium mole fraction along the length of $\text{Ga}_{1-x}\text{In}_x\text{Sb}$ crystals for different starting melt compositions, assuming completely homogeneous melt at all times. In these plots, the difference in segregation coefficient with change in melt composition was taken into account. The segregation coefficient as a function of alloy composition was extracted from the phase diagram of GaInSb, as depicted in Fig. 10.18. As clearly seen in Fig. 10.21, the solid composition changes continuously in the crystal due to changes in the melt composition. The rate at which the alloy composition changes along the crystal is dependent on the extent of separation between the liquidus and solidus curves, which is a material-dependent

Fig. 10.21 Theoretical gallium concentration along the growth axis for $\text{Ga}_x\text{In}_{1-x}\text{Sb}$ crystals grown from different starting melt compositions (under normal freezing conditions). The fractions next to each curve represent the gallium mole fraction in the starting melt

property. A narrow gap between the two curves is desirable for growing homogeneous crystals and avoiding defects such as cracks in the crystals, as discussed in the next section.

The other extreme for alloy segregation behavior is observed under steady-state diffusion in a convection-free melt. This is represented by the well-known equation for diffusion-controlled segregation as [10.80, 82]

$$\frac{C_s(x)}{C_0} = k_0 + (1 - k_0) \left[1 - \exp \left(-\frac{k_0 R x}{D} \right) \right], \quad (10.7)$$

where $C_s(x)$ is the alloy concentration in the solid at a distance x measured from the beginning of the growth. In this scenario, the alloy composition in the diffusion boundary layer increases with time since there is no convective flow in the melt to extract the species from the diffusion boundary layer. This leads to a rapid increase in the alloy composition in the solid (initial transient) followed by a uniform region in the crystal. Figure 10.22 shows a typical diffusion-controlled alloy composition profile in a solid (10.7). For the sake of comparison, a normal freezing curve (10.4) with the same segregation coefficient has been included. While plotting (10.7), the parameter x has been normalized to the solidified fraction g . The uniform region in the diffusion-controlled profile appears very attractive for growing uniform ternary crystals. However, the technical problem lies in the fact that it is very difficult to achieve pure diffusion-controlled conditions. This would require complete elimination of convec-

Fig. 10.22 Theoretical alloy composition profiles along the growth axis for crystals grown with complete melt mixing (normal freezing) and in the absence of melt convection (diffusion-controlled growth)

tion in the melt. Melt convections can be reduced by using magnetic fields [10.83–85], submerged baffles in the melt [10.86, 87], and under microgravity conditions [10.88–93]. However, these approaches have not been used in large-scale ternary crystal growth. There are other technical issues such as composition and length of the diffusion boundary layer necessary for growing ternary crystals with alloy compositions that are far from the binary compositions. Hence for the rest of this chapter, we will focus on the alloy composition changes that are typically seen in experiments with normal freezing conditions.

10.8 Crack Formation in Ternary Crystals

10.8.1 Phenomena of Crack Formation

One of the consequences of the alloy segregation is the cracking of the crystals during growth. If the growth rates are not low enough, constitutional supercooling occurs close to the liquid–solid interface, resulting in composition fluctuation and sudden transition from single to polycrystals. The local compositional inhomogeneity in the solid along with the wide difference in the lattice constants and the thermal expansion coefficients of constituent binary compounds introduces considerable strain, and invariably leads to cracking of the crystals. For the GaInSb system, the lattice parameter varies from 6.096 Å (for GaSb) to 6.479 Å (for InSb) and the thermal expansion coefficient from 7.75×10^{-6} to $5.37 \times 10^{-6} \text{ } ^\circ\text{C}^{-1}$ [10.1]. Figure 10.23

Fig. 10.23 Theoretical misfit strain gradient versus fraction of solidified melt calculated from the theoretical concentration curves shown in Fig. 10.21 for $\text{Ga}_x\text{In}_{1-x}\text{Sb}$ crystals

Fig. 10.24 Typical microcracks seen in ternary III–V crystals. The composition of the wafer shown here is $\text{Ga}_{0.7}\text{In}_{0.3}\text{Sb}$

shows the theoretical misfit strain gradient curves calculated using the theoretical alloy composition profiles shown in Fig. 10.21 and the lattice parameter a_0 for each composition using Vegard's law (10.1). It has been empirically observed that crystals inevitably crack if the misfit strain gradient exceeds 1–2% [10.17]. It is obvious that an alloy system with larger separation between the solidus and liquidus line has higher strain gradient than those with smaller separation. Moreover, cracking may occur even below 1% misfit strain gradient if there is a thermal strain caused by the large temperature gradient in the solid or during rapid cooling for the crystals. Figure 10.24 shows microcracks in a wafer sliced from a $\text{Ga}_{0.7}\text{In}_{0.3}\text{Sb}$ polycrystal grown using the vertical Bridgman method. The growth conditions used for this crystal were not optimized for avoiding cracks (as discussed below).

Cracks in crystals make the wafers completely unusable for any basic research or device applications. Hence eliminating cracks in the crystals by optimizing growth conditions is the first task for any ternary crystal growth. The cracks can be somewhat eliminated by zone leveling, slow cooling or prolonged annealing of the solidified ingot [10.17]. However, the concentration gradient does not smoothen completely by thermal treatment due to the low solid-state diffusion coefficients of III–V compounds. Hence microscopic cracks and stresses remain. Cracks can be avoided if and only if smooth change in alloy composition is ensured in the

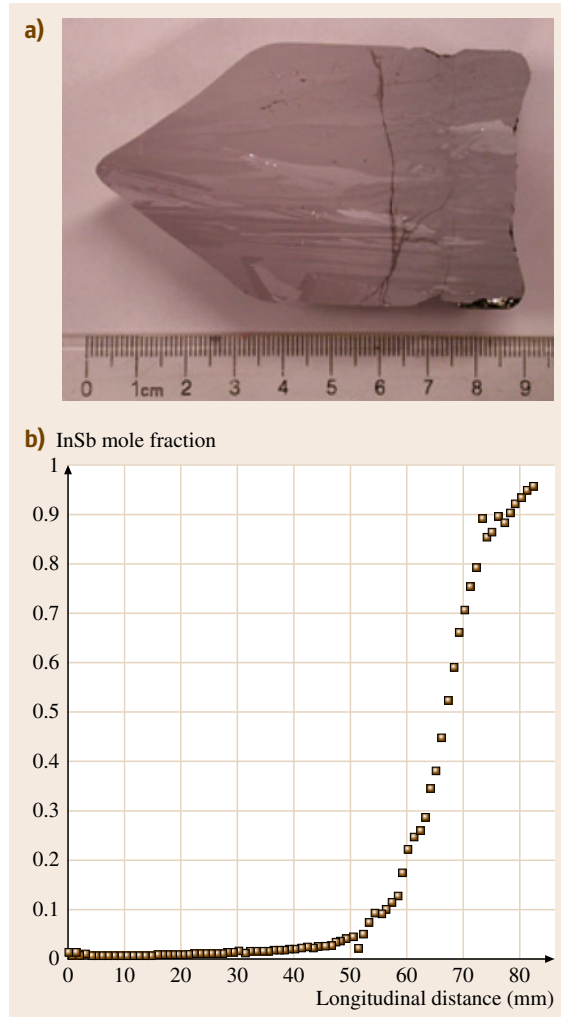

Fig. 10.25 (a) Cross section of a GaInSb crystal showing strain-gradient-related cracks and (b) the longitudinal composition profile measured along the center of the crystal

crystals during growth. Referring to Fig. 10.23, strain-related cracks originate in the crystal where the strain gradient exceeds 1–2%, as shown by the horizontal dashed line. For a crystal grown with starting gallium mole fraction of 0.7 in the melt, cracks should appear when the fraction solidified (G) is close to 60%. This has been experimentally confirmed during growth of GaInSb . Figure 10.25a shows a cross section of a crystal with a visible crack around 6 cm from the bottom of the crystal. This coincides with the longitudinal composition profile measured in the same crystal as shown in Fig. 10.25b. The region where the composition starts

changing rapidly (between 60 and 70 mm) is exactly where the crack in the crystal appears. It is interesting to observe that the cracks propagate across multiple grains (seen in both Figs. 10.24 and 10.25a) and the crack network cannot be correlated with the polycrystalline grain structure. Strain-related cracks seem to occur after the solidification front (melt–solid interface) had crossed the respective position. This clearly indicates that these cracks are not due to constitutional supercooling during growth, but are rather due to strain in the crystal. Rapid change in composition such as in Fig. 10.25b can also lead to constitutional supercooling and interface breakdown with sudden change in the grain structure and the appearance of cracks. However these cracks are easily distinguishable from strain-related cracks. Since there are two origins of cracks, different crystal growth conditions are necessary to eliminate them.

10.8.2 Elimination of Cracks

Misfit strain-related cracks are related to the rate at which the alloy composition and more importantly the lattice parameter and other physical properties such as thermal expansion coefficient change along the length of the crystal. Hence these cracks can be eliminated by ensuring gradual changes in alloy composition that will result in a strain gradient lower than that which initiates cracking. This is especially important during the seed formation process, as described in the next section. Since the materials properties for binary compounds vary significantly, the density of cracks varies for each ternary compound. Theoretical analysis of strain gradient as in Fig. 10.23 coupled with experimental trials is necessary to determine the compositional gradient in the crystal that will not lead to cracking.

Cracks originating from the constitutional supercooling process can be eliminated by avoiding supercooling during growth. This requires thinning the diffusion boundary layer at the melt–solid interface. Supersaturation in the boundary layer results in spurious nucleation and the formation of polycrystals [10.94,95]. A boundary layer with a diffusion-controlled (exponential) concentration distribution ahead of the growth interface causes constitutional instability. A region of constitutional supercooling emerges if the equilibrium liquidus temperature gradient exceeds the actual temperature gradient in the melt at the solid–liquid interface [10.82]. The composition of the diffusion boundary layer (enriched with the lower-melting-point binary compound such as InSb during the growth of

GaInSb) depends on the melt volume, the growth rate, and the degree of melt stirring. Theoretical analysis [10.80] has shown that, for preventing constitutional supercooling, the ratio of the temperature gradient in the melt near the growth interface (G) to the growth rate (R) should exceed a critical value given by

$$\frac{G}{R} \geq \frac{mC_0(1-k_0)}{k_0D}, \quad (10.8)$$

where m is the slope of the liquidus in the phase diagram.

Since avoiding constitutional supercooling is absolutely necessary during ternary growth, the role of melt stirring is crucial. Melt stirring can also enhance the growth rates by thinning the diffusion boundary layer at the growth interface. Melt stirring and homogenization can be achieved by natural convection, diffusion, and forced convection. Mass transport by natural convection takes place in most growth experiments due to the thermal convection caused by the temperature differences as well as the solutal convection caused by the density difference arising from the variation in solute concentration [10.96]. The natural convection and diffusion phenomena are weak. As a result of this, growth rates that are necessary for crack-free crystals are very low. Figure 10.26 shows the experimental crystal growth rates that were found to result in crack-free GaInSb crystals of different composition [10.18]. It is clear from the figure that, by using forced convection in the melt,

Fig. 10.26 Growth rate necessary for crack-free GaInSb crystals as a function of InSb mole fraction in the solid: crystals grown using temperature gradient of (◆) 10 °C/cm and (◻) 20 °C/cm without forced convection; (▲) crystals grown using 10 °C/cm temperature gradient with forced convection in the melt

the growth rates can be increased. For melts without any forced convection, a larger axial temperature gradient ($20\text{ }^{\circ}\text{C}/\text{cm}$) helps to increase growth rates for crack-free crystals. This is expected from *Tiller's* analysis [10.80], as discussed earlier. While increasing the axial temperature gradient helps to avoid constitutional supercooling, it increases the melt–solid interface curvature, due to which the radial composition profile in the wafers varies (as discussed later). Hence a lower temperature gradient is necessary for the growth of ternary compounds, which also helps in eliminating strain-related cracks in the crystal. To avoid constitutional supercooling under a lower temperature gradient, either the crystal growth rate needs to be decreased or melt stirring (by forced convection) needs to be enhanced. There are no thermal and solutal convection cells in the homogenized solution due to stirring and thus the supersaturation is not likely to go beyond the critical values for spontaneous nucleation. The second effect of homogenization is that the growing crystal always faces a homogeneous diffusion field, and thus inhomogeneities in crystals such as striations are avoided or decreased to a minimum level. Forced convection leads to a decrease in the metastable region and supersaturation. This decrease in supersaturation corresponds to a narrowing of the metastability range, so that no enhanced spontaneous nucleation is seen. Stirring decreases the diffusion boundary layer and reduces the inhomogeneous supersaturation across the growing crystal, which allows a faster stable growth rate than without stirring [10.97].

Fluid mixing patterns used for forced convection can be very complicated and significantly impact on crystalline quality. Melt mixing schemes reported in the literature [10.18, 25, 98, 99] during ternary crystal growth include: unidirectional rotation of the crucible, the accelerated crucible rotation technique (ACRT), and mixing the melt using baffles and stirrers. Unidirectional rotation, even at high rotation rates (100–200 rpm), does not result in effective mixing for large-diameter crystals (50 mm and higher). In ACRT, the crucible is periodically accelerated and decelerated (around the growth axis) to promote efficient mixing of the melt, as shown in Fig. 10.27. However, there can be dead (unmixed) zones even in a thoroughly mixed melt, especially at the center of the crystal [10.99]. These types of unmixed zones lead to compositional fluctuations in the grown crystals. Hence it is essential to optimize the rotation schemes for each crucible diameter, melt size, and fluid viscosity in the ACRT scheme. In the baffle mixing scheme [10.25], the melt is homogenized very efficiently either by rotating the baffle in

Fig. 10.27 Accelerated crucible rotation rates used for melt mixing and solute transport during vertical Bridgman growth of ternary crystals

the melt or by translating the baffle perpendicular to the growth interface, similar to shown in Fig. 10.10b (for polycrystalline charge synthesis). In the case where the baffle is translated perpendicular to the growth interface, obtaining single crystals is quite difficult due to thermal fluctuations at the melt–solid interface. Very small-sized grains are observed by using this process. In the case of stirrer mixing, a stationary stirrer is held inside the melt with a uniformly rotating crucible. The stirrer also helps in efficient solute transport during solute feeding processes (discussed later). The stirrer mixing scheme is simple and can be easily adopted for large melt mixing. In the future, it will be worthwhile investigating the effect of magnetic field stirring on the crack elimination process.

Fig. 10.28 Crack-free ternary wafer of $\text{Ga}_{0.76}\text{In}_{0.24}\text{Sb}$

10.8.3 Crystal Growth Rate for Crack-Free Ternary Crystals

As is evident from Fig. 10.26, crystal growth rates can be enhanced by a factor of four by efficient melt mixing. Typical growth rates for the GaInSb system are in the range of 0.3–0.5 mm/h (with 10 °C/cm thermal gradient). By using the optimized ACRT scheme, as shown in Fig. 10.27, the growth rate for crack-free crystals can be increased to 2 mm/h under the same thermal gradient (10 °C/cm). Figure 10.28 shows a crack-free polycrystalline wafer of Ga_{0.76}In_{0.24}Sb grown using the ACRT scheme. The growth rate was ≈ 1 mm/h, similar to that used for the cracked wafer

shown in Fig. 10.24. In general, for III–V ternary crystals, with an axial temperature gradient of ≈ 10 °C/cm, the maximum growth rate for crack-free single crystals is in the range of 0.02–0.5 mm/h, depending on the specific alloy system and its composition [10.18]. These rates are significantly lower than the binary growth rates (1–3 mm/h) under similar thermal gradient. A delicate balance between heat and mass transport strategies is necessary for ternary single-crystal growth without cracks. By using efficient melt stirring, the crystal growth rates for ternary materials can approach those for binary compounds grown under the same temperature gradient and group V overpressure.

10.9 Single-Crystalline Ternary Seed Generation Processes

For III–V ternary alloys, single-crystal growth poses a major challenge. Unlike for binary compounds, growth of spontaneously nucleated single-crystal ternary seeds such as from the tip of a crucible in the Bridgman method has not been possible. The preferred method for generating a seed of any ternary composition is by starting from a binary seed. However there is a major criterion that needs to be satisfied. It has been empirically observed that, for alloy systems with wide lattice mismatch between the end binaries (GaAs–InAs, GaSb–InSb, InAs–InSb, etc.), the first-to-freeze section of the crystal must have a composition less than or equal to 5 mol % with respect to the seed in order to maintain single-crystallinity [10.19–21, 100]. For example, during the growth of single-crystal Ga_{1–x}In_xAs on a GaAs seed, the first-to-freeze Ga_{1–x}In_xAs should have $x < 0.05$ [10.100]. With $x > 0.05$, polycrystalline growth occurs on a single-crystal seed [10.100]. Hence the compositional grading during ternary seed generation needs to be carefully controlled to obtain single-crystal seeds.

There are three common ways of generating a compositionally graded ternary seed starting from a seed of a binary compound, as discussed below.

10.9.1 Bootstrapping Method

The most common method is the *bootstrapping* process, wherein seeding is initiated from a binary seed and successive experiments are performed with increasing solute concentration to reach the target alloy composition in the seed. Figure 10.29 schematically depicts the axial composition in a single-crystal GaInAs seed

generated by the bootstrapping method. For example: to generate a Ga_{1–x}In_xAs seed, one would start from a GaAs or InAs seed and grow successive ingots of step-graded GaInAs. The maximum allowable step-like change in composition between the last-to-freeze of any ingot with the first-to-freeze of the next ingot must be equal or less than 5 mol %, as shown in Fig. 10.29. Due to change in the segregation coefficients with alloy composition (dictated by the pseudobinary phase diagrams), there is an increase in the InAs concentration during growth beyond each step. Bonner and coworkers [10.101, 102] employed this method to grow ternary seeds of Ga_{1–x}In_xAs up to $x = 0.12$ by using the Czochralski technique. Tanaka et al. [10.23] employed multistep pulling solute feeding Czochralski

Fig. 10.29 Composition profile (schematic) of a GaInAs single-crystal seed generated by the bootstrapping process

method to grow $\text{Ga}_{1-x}\text{In}_x\text{Sb}$ single crystals using composition steps of $x = 0.04, 0.08, 0.12$, and 0.18 . Though the bootstrapping technique is the most straightforward way of generating single-crystal ternary seeds, it has several limitations. First of all, seed generation with concentrated alloy composition (e.g., $x = 0.5$) can be time consuming since the step in alloy composition in each growth run can only be 5 mol %. For vertical Bridgman growth, it is very difficult to use this method. The melt composition for successive growth in contact with the previous seed needs to be carefully monitored to avoid excessive dissolution of the seed crystal.

10.9.2 Directional Solidification by Normal Freezing

This method is based on the intrinsically changing axial composition profile in a crystal that has been directionally solidified by normal freezing, as depicted in Fig. 10.21 [10.100, 103, 104]. The process is shown schematically in Fig. 10.30a–d. In this process, a binary seed such as GaAs is used. A GaInAs melt is prepared by dissolving InAs and GaAs with the appropriate melt composition that would lead to a first-to-freeze ternary crystal region with 5 mol % compositional step as required for the ternary seed generation process. The melt is directionally solidified by Bridgman or gradient freezing method to obtain a ternary graded

Fig. 10.31 Composition profile (schematic) in a directionally solidified ternary single-crystal seed

crystal. Figure 10.31 schematically depicts the axial InAs composition profile in a vertical Bridgman grown GaInAs crystal. Depending on the composition of the seed necessary for the actual crystal growth experiment, the crystal could be sliced at an appropriate axial position along the length of the crystal. The main problem with this approach is when the composition starts changing rapidly in the crystal; microscopic fluctuation of the composition and polycrystallinity occur due to constitutional supercooling unless the growth rate is significantly reduced. Hence only a part of crystal is sin-

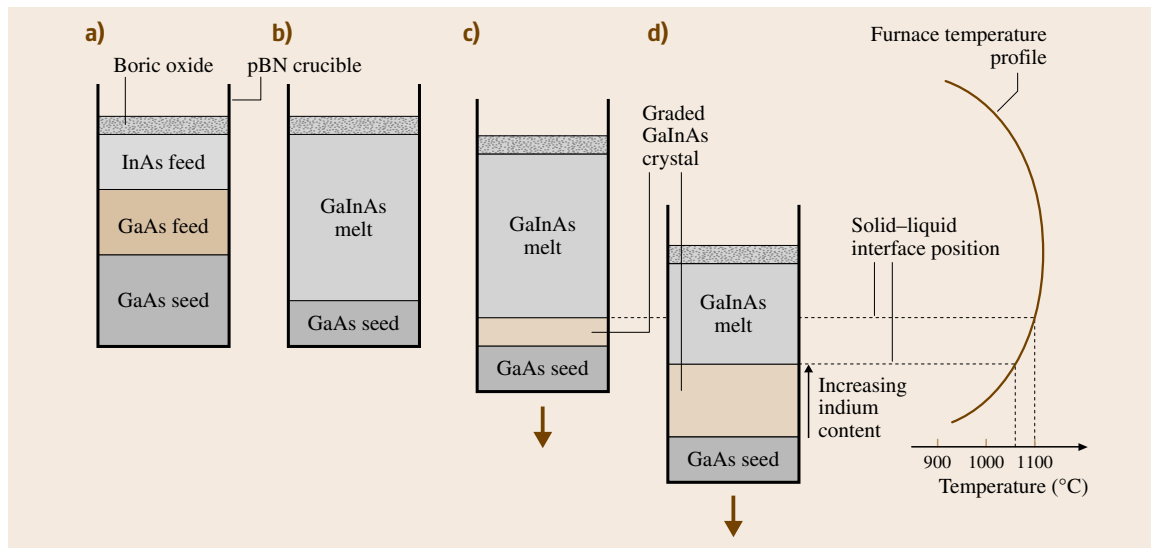

Fig. 10.30a–d GaInAs single-crystal seed generation by vertical Bridgman method (the arrows in (c) and (d) indicate the lowering of the crucible to the cold zone of the furnace during crystal growth)

gle and a bootstrapping process is necessary to change the composition of the seed beyond the point where the single- to polycrystal transition occurs. Even if one manages to grow a complete single crystal by reducing the growth rate, using a seed with a steep change in composition still remains a problem. During the subsequent crystal growth experiment, the seed needs to be dissolved slightly by contact with the ternary melt. However, any dissolution in the steep compositionally graded region will change the composition of the seed at the growth interface. Hence using the compositionally graded seed for a lattice-matched crystal growth experiment is not practical.

10.9.3 Directional Solidification by Solute Diffusion and Precipitation

This process is based on solute diffusion in the melt due to a concentration gradient [10.18, 98, 105, 106]. A schematic diagram of the approach is shown in Fig. 10.32a–d for growing GaInAs seeds. For GaInAs graded seed growth, the lower melting binary (InAs) is used as a seed. The charges in the crucible are stacked as shown in Fig. 10.32a. The crucible is placed in a temperature gradient in such a way that the InAs feed and a portion of the InAs seed remelts to dissolve a portion of the GaAs feed, forming a GaInAs melt. While selecting the temperature profile in the furnace, care should be taken to avoid melting of the GaAs feed. The dissolved GaAs from the feed diffuses towards the seed due to the concentration gradient. Once the solute content in the melt at any point reaches the solidus composition (corresponding to the solidus temperature), solidifica-

Fig. 10.33 Composition profile (schematic) of a GaInAs single-crystal seed generated by solute dissolution and diffusion

tion occurs. The growth rate is thus limited by the solute diffusion rate. During the growth, neither the crucible nor the furnace is translated. The composition profile in the graded crystal will depend on the temperature profile imposed by the furnace and the solidus curve in the pseudobinary phase diagram. As the GaAs in the melt precipitates and the crystal grows, the melt gets richer in InAs and hence more GaAs is dissolved from the feed. Ultimately, a crystal is obtained with compositional grading from InAs towards GaAs. Theoretically, if the furnace temperature profile matches the solidus temperature curve of the phase diagram, the compositional grading in the crystal will be linear, as depicted in Fig. 10.33.

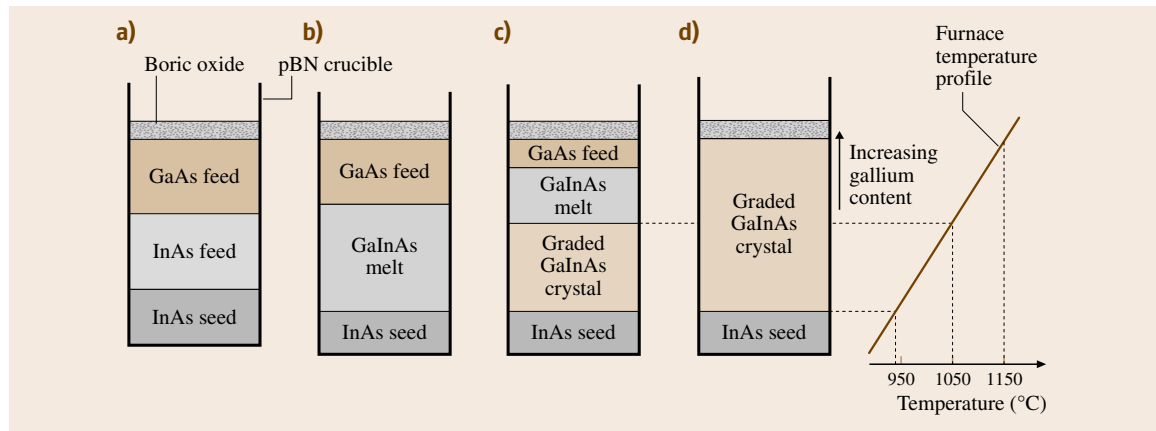

Fig. 10.32a–d GaInAs single-crystal seed generation using solute dissolution and diffusion method (with stationary crucible and furnace)

10.9.4 Growth of Lattice-Mismatched Ternary on Binary Using Quaternary Grading

One of the interesting aspects of the thermochemistry shown in Fig. 10.20 is the growth of ternary compounds from quaternary melts [10.29, 30, 78]. The concept is shown schematically in Fig. 10.34a. By using a GaAs seed and a GaInAsSb melt of a specific composition at a specific growth temperature, one can grow a GaInAs ternary crystal of uniform composition. The composition of the uniform ternary crystal is dependent on the quaternary melt composition and growth temperature. By carefully analyzing the region between the ternary crystal and the binary seed, a quaternary transition region has been observed where the composition changes from the binary to the ternary. The thickness of this graded quaternary region can be in the range of 10–100 μm , depending on the melt composition. In this process, no efforts are made to control the growth conditions to grow the graded quaternary intermediate layer. The compositional grading occurs spontaneously during the growth process. Figure 10.34b shows a compositionally homogeneous $\text{Ga}_{0.86}\text{In}_{0.14}\text{As}$ grown on GaAs substrate using a quaternary $\text{Ga}_{0.07}\text{In}_{0.93}\text{As}_{0.06}\text{Sb}_{0.94}$ melt at 700 $^{\circ}\text{C}$ [10.78]. The GaInAs ternary region does contain residual Sb (less than 1 mol %). However, for all practical purposes, it can be considered a ternary compound. The effect of residual antimony on the lattice parameter and bandgap is negligible. This process could be used in the future to grow ternary seeds of a desired

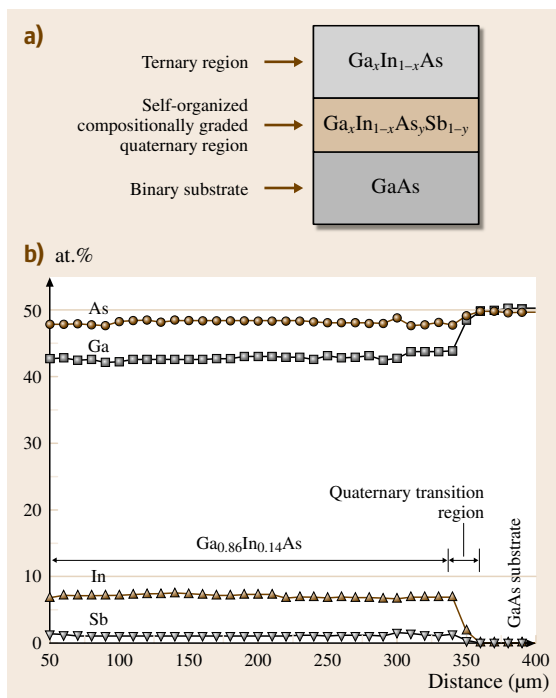

Fig. 10.34 (a) GaInAs seed generation using a self-organized quaternary grading method and (b) experimental composition profile for $\text{Ga}_{0.86}\text{In}_{0.14}\text{As}$ grown on GaAs

composition starting from a binary seed and quaternary melt by simple Bridgman or gradient freezing method without the need for any sophisticated grading procedures.

10.10 Solute Feeding Processes for Homogeneous Alloy Growth

Having grown a ternary single-crystal seed of the desired composition, the next step is to grow a ternary crystal of homogeneous composition from which a large number of wafers (of the same composition) can be sliced. We know that the melt composition as well as the ternary crystal composition changes continuously during the experiment (due to alloy segregation). Hence to grow homogeneous crystals, it is necessary to develop melt replenishment processes that can maintain the composition of the melt constant over the entire duration of the crystal growth experiment. In this section, we discuss the various melt replenishment methods and their limitations.

10.10.1 Growth from Large-Volume Melts

One simple idea would be to grow a small crystal from a huge volume of melt [10.107]. Referring to Fig. 10.21, few wafers of constant composition could be extracted from the first-to-freeze section of the crystal. The melt could then be reused for the next experiment by replenishing with fresh material to account for the extracted wafers. However, this is not a practical solution. Contamination of the melt by impurities from repeated use, the large crystal growth systems required, and the possibility of damaging the crucible during cooling of the melt make this process unattractive for ternary substrate

technology. For large-scale crystal growth production, it is desirable to consume the entire melt during a single experiment. Hence, growth from large-volume melts is not practiced for commercial applications.

10.10.2 Solute Feeding Using Double-Crucible Configuration

Melt replenishment during growth is also known as solute feeding. Many interesting solute feeding concepts have been tried by different researchers. The simplest of these processes is the solute feeding in the Czochralski (CZ) configuration [10.108–112]. Figure 10.35a shows

Fig. 10.35a,b Solute feeding in (a) single-crucible and (b) double-crucible Czochralski (CZ) growth configurations

a schematic diagram of this process for GaInAs growth. As the melt becomes depleted in GaAs, the feed rod is inserted to dissolve and maintain the composition of the melt at the liquidus composition. The problem with this process is the uncontrolled dissolution of the feed rod. If the radial temperature in the growth melt is uniform, the feed rod dissolves slower than the crystal pulling rate. This is due to the long duration it takes for the melt to uniformly develop the undersaturation level after the GaAs is depleted by the growing crystal. Hence the feed rod tends to dissolve at a slower rate than the rate at which the GaAs is depleted in the melt. This leads to fluctuation in the composition of the growing crystal. On the other hand, if the radial temperature at the edge of the crystal is increased to enhance the dissolution of the feed rod, rapid transport of GaAs to the growth interface often leads to rapid polycrystalline growth. Hence the feed dissolution rate and GaAs depletion rate need to be matched. This is quite challenging given the fact that the melt height changes during growth in the CZ technique, and thus so does the radial temperature gradient. To restrict the rapid transport of solute from the feed to the growth interface, a double-crucible CZ method as shown in Fig. 10.35b can be employed. In this configuration, the depleting component can be added to the outer crucible instead of the inner crucible. The temperature of the outer crucible is higher than that of the inner crucible, due to which the solubility of the GaAs feed in the GaInAs melt is higher. The narrow gap between the two crucibles controls the feeding rate of GaAs from the outer to inner crucible. This method also shares one of the limitations of the single-crucible CZ technique: once the outer melt is supersaturated with GaAs, the dissolution of the feed rod stops. The outer melt supersaturation level decreases only when the GaAs has been transported to the inner melt and the inner and outer melt have homogenized. Hence the feed rod does not dissolve continuously during the growth, which leads to fluctuations in the alloy composition in the crystal.

Variations on the double-crucible CZ configuration (refer to Fig. 10.36) have been attempted to control the solute transport rate between the inner and outer crucibles [10.23, 106, 113–116]. In both of these configurations, a piston attached below the outer crucible is used to keep the volume of the melt constant in the inner crucible. The diameter (Fig. 10.36a) or the length (Fig. 10.36b) of the channel is varied to control the solute feeding rate. The limitation with these processes is the blocking of the channels by the transporting solute. A change in liquidus temperature occurs along the

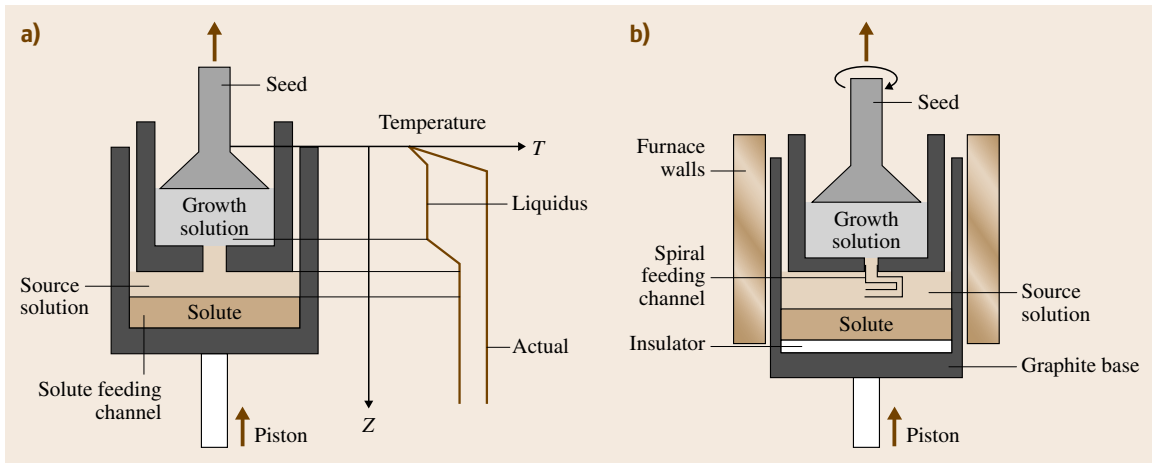

Fig. 10.36a,b Solute feed rate control in the double-crucible CZ method by optimizing (a) feeding channel diameter and (b) feeding channel length

length of the supply channel, as shown in Fig. 10.36a. This leads to precipitation of the solute in the channel towards the lower-temperature side. If the channel width is made larger to solve this problem, back-diffusion of species from the inner to the outer crucible takes place, which leads to variations in the composition of the grown crystal. Another problem is the optimization of the length of the spiral feeding channel (Fig. 10.36b). The diffusion rate of species in the channel dictates the growth rate of the crystal. A shorter channel leads to

back-diffusion of species from the inner to the outer melt, changing the composition of the growth solution. On the other hand, a longer channel leads to slow diffusion of species from the outer to the inner melt.

10.10.3 Solute Feeding in the Vertical Bridgman Method

The double-crucible CZ concept for solute feeding can be applied to the Bridgman or gradient freeze type

Fig. 10.37a–d Continuous solute feeding during vertical Bridgman growth

methods [10.21, 104]. Figure 10.37 shows a continuous solute feeding process during vertical Bridgman growth of GaInAs. In this configuration, a ternary single-crystal seed of GaInAs of the desired composition (solidus composition) is placed in a flat-bottomed crucible. A GaInAs polycrystalline homogeneous feed with the liquidus composition is placed on the seed. A GaAs polycrystalline solute feed is stacked on the GaInAs feed, separated by a quartz plate with a hole (Fig. 10.37a). The entire stack is then heated to the

growth temperature to melt the GaInAs feed and a small portion of the feed (Fig. 10.37b). The crucible is translated as in a vertical Bridgman growth process to initiate the crystal growth (Fig. 10.37c). The composition of the growing crystal is same as the ternary seed. The GaAs that is being depleted in the growth melt is continuously replenished by the feed at the top. The diameter of the hole restricts the dissolution rate of the GaAs feed. This helps to avoid rapid transport of GaAs from the feed to the growth interface, thus eliminating the possibility of polycrystalline growth [10.104]. The technical challenge with this configuration is the variation in the melt level during growth due to differences in the density of the melt versus the solid. When the GaInAs feed melts, the melt height lowers and the GaAs feed does not touch the melt unless a special mechanism is used to lower the feed. When the crystal grows, the solid expands, due to which the melt height increases. Hence there should be proper mechanism for moving the GaAs feed up into the crucible.

10.10.4 Solute Feeding by Crucible Oscillation

The method for synthesizing GaSb and InSb in sealed crucible as depicted in Fig. 10.9 can be adopted to perform solute feeding process during ternary growth [10.117]. Figure 10.38 shows the rocking furnace configuration for GaInAs growth. At one end of the crucible, the GaAs seed is placed, onto which a graded-composition GaInAs crystal is first grown towards the lower-temperature region of the furnace (as in the Bridgman method). Thereafter the furnace is tilted periodically such that the GaInAs melt touches the GaAs feed to replenish the depleted species. The crucible is continuously translated to continue the growth. Since the GaAs level in the ternary melt is kept constant by dissolving the feed, the composition of the grown crystal is homogeneous. For radial compositional homogeneity, the crucible can be rotated during growth. In this process, the temperature gradient across the crucible length plays a significant role in the crystalline quality. If thermal fluctuation occurs due to the oscillating melt, the grain size could be extremely small in the crystal. To avoid excessive feed dissolution or rapid precipitation at the growth interface, a low axial temperature gradient is desirable. However this increases the probability of constitutional supercooling. Hence efficient melt mixing by forced convection (continuous

Fig. 10.38 Solute dissolution and feeding in a rocking furnace assembly

Fig. 10.39a–d Growth of homogeneous ternary by sequential normal freezing and zone growth methods

oscillation) in conjunction with a slow growth rate is necessary for this process.

10.10.5 Growth Using Compositionally Graded Feed

The graded concentration solute feeding process is depicted in Fig. 10.39 [10.118]. In this method, starting from a homogenous melt of composition C_0 , a crystal is first grown using the Bridgman or gradient freezing method. The axial alloy composition in the grown crystal is shown in Fig. 10.39b. According to segregation phenomenon, the composition in the crystal starts from kC_0 (k being the segregation coefficient) and continuously builds up beyond C_0/k . The crystal is then reversed and a traveling zone heater is traversed across the crystal starting from the C_0/k side. The final composition in the crystal is uniform and equal to C_0 . A traveling heater method (THM) can also be used to practice this concept [10.119]. This method needs a purely diffusive growth condition. Such conditions can only be found in microgravity situations. Convective flow in the liquid zone will change the solute concentration and result in nonuniform growth. Magnetic fields can be used to dampen convective flows. However for large-scale ternary substrate production, this method is not suited.

10.10.6 Periodic Solute Feeding Process

From the processes described above, it is clear that any large-scale ternary crystal growth process will require mechanisms for precise control of melt composition. Another technical problem is the preparation of the growth melt during the experiment. Ensuring that the melt composition is in equilibrium with the seed composition is crucial for avoiding excessive seed dissolution. The rate of solute dissolution and transport to the growth interface also needs to be controlled to achieve high crystalline quality and growth rates suitable for commercial applications. To address all of these technical issues collectively, the process shown in Fig. 10.40 has been developed and successfully employed for large-diameter ternary crystal growth. In this process, starting from a binary seed, the graded ternary seed and the homogeneous ternary crystal is grown in a single experiment. The schematic of the experimental growth configuration and crystal growth sequence for GaInSb is shown in Fig. 10.40a–d [10.28, 98, 120, 121].

To start with, a InSb single-crystalline seed is placed at the bottom of the crucible along with InSb polycrystalline charge. A GaSb polycrystal feed is suspended from the top of the growth chamber. After heating and stabilizing the furnace to obtain a specific temperature gradient, the crucible is raised into the furnace.

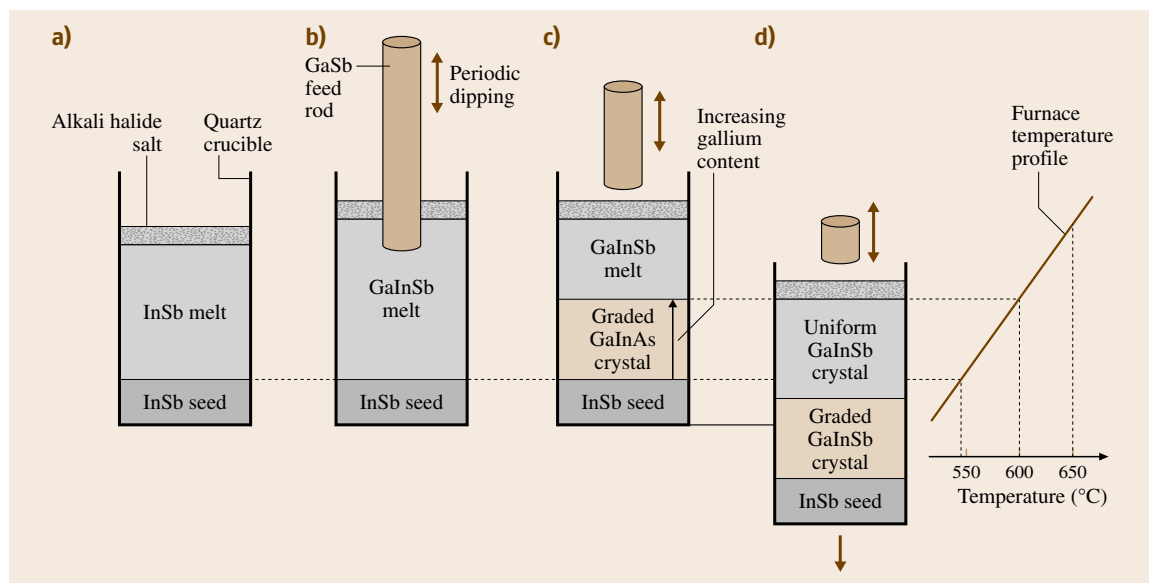

Fig. 10.40a–d Periodic solute feeding process for growth of graded-composition ternary seed and homogeneous ternary crystal in a single experiment by sequentially using solute diffusion and normal freezing processes

The InSb feed melts along with part of the InSb seed to obtain a melt–solid interface (Fig. 10.40a). At this point, the GaSb feed is lowered and allowed to touch the top of the InSb melt for a few seconds. The crucible is set to perform accelerated crucible rotation (ACRT), as shown in Fig. 10.27, and a homogeneous GaInSb melt is prepared (Fig. 10.40b). The GaSb feed is lowered periodically to touch the GaInSb melt. The dissolved species is transported rapidly to the InSb seed interface as a result of ACRT melt mixing. Crystal growth is initiated in the crucible as a result of the increasing level of the solute concentration at the solid–liquid interface with time. When the solute concentration in the melt near the seed interface reaches the liquidus composition, precipitation takes place and GaInSb starts growing on InSb (Fig. 10.40c). The crucible is kept at the same position in the furnace while the ACRT continues. As the GaSb feed is periodically lowered to touch the melt for few seconds, more solute is dissolved and transported to the growth interface and the crystal growth continues. Crystal grown by this method is compositionally graded along the growth axis with increasing gallium concentration in $\text{Ga}_{1-x}\text{In}_x\text{Sb}$ (decreasing indium concentration). The rate of compositional grading is decided by the solidus temperature in the pseudobinary phase diagram and the axial furnace temperature gradient. The axial composition in the crystal is graded until a desirable alloy composition is achieved and then a homogeneous composition crystal length is grown. During the compositionally graded crystal growth, the melt–solid interface automatically rises from the cooler to the hotter zone in the furnace. Thus the melt–solid interface shape changes continuously during the growth. The effect of temperature gradient on the melt–solid interface shape and the radial compositional variation will be discussed in the next section. To grow crystal with axially uniform composition, the crucible is translated into the lower-temperature zone of the furnace while the GaSb feed dissolution is continued by the periodic dipping method. While the GaSb at the melt–solid interface is depleted by preferential incorporation in the crystal, it is being replenished by the feed dissolution. Hence the melt–solid interface remains at the same position in the furnace until the entire melt has solidified (Fig. 10.40d).

The periodic solute feeding process described above in conjunction with efficient melt mixing provides complete control over the composition profile in the graded seed and the homogeneous crystal [10.120]. The entire experimental process could be automated using programmable stepper motors for the periodic solute

feeding, ACRT, and crucible translation processes. The main advantage of this process is the single experiment in which a ternary homogeneous crystal of any alloy composition can be obtained starting from a binary single-crystal seed and polycrystalline binary feed materials. For high-quality crystal growth, the periodic solute feeding process parameters need to be fine-tuned. This is necessary to precisely control the rate at which solute depletes and replenishes in the melt. The major process parameters that affect the crystalline quality include: the solute dipping time and frequency, the mixing strategy of the melt for solute transport, and the thermal gradient in the melt. Dipping time denotes the actual time that the melt is in contact with the feed. This determines the amount of feed introduced in the melt over one period of the dipping cycle. Due to the temperature gradient in the melt, the top of the melt (higher-temperature zone) is usually undersaturated. Hence there exists a danger of uncontrolled dissolution if the solute feeding rod is dipped for longer than the required time. Thus precise control of dipping time is required. Excess dissolution of the solute can promote random nucleation in the entire melt volume. Additionally, this can lead to an oversupply of the solute to the growth interface leading to small grains or causing a change in grain structure, as shown in Fig. 10.41. Dipping frequency defines the period of the dipping cycle and should depend on the growth rate. It takes finite time for the solute to reach the growth surface. Further, the growth kinetics determines the actual growth rate. The thermal gradient in the melt dictates the melt homogenization efficiency. For lower thermal gradients, the time for melt homogenization is longer than for high thermal gradient. Hence the dipping frequency needs to be lower for lower thermal gradients in order to prevent constitutional supercooling and so-

Fig. 10.41 Transition from large to small grains due to uncontrolled (rapid) solute feeding process during growth

lute precipitation in the melt. Mixing of the melt greatly affects the crystal growth. Efficient mixing can remove the excess solute rejected at the growth interface in less time than without mixing, thereby decreasing the possibility of constitutional supercooling. This suppresses the chances of interface breakdown, leading to conditions conducive for single-crystal growth. Based on experimental crystal growth results, a set of optimized periodic solute feeding parameters for GaInSb growth include: solute contact area of 20 mm, solute dipping time of 2–3 s, solute dipping frequency of 3–4 times per hour, temperature gradient near the melt–solid interface of 15 °C/cm, and ACRT melt mixing process. Figure 10.42 shows elemental composition profiles of Ga, In, and Sb for the graded GaInSb seed (shown in Fig. 10.41) grown using the periodic solute feeding process with the optimized parameters. The superior control of the composition profile shown in this diagram clearly demonstrates the effectiveness of the periodic solute feeding process. Beyond 47 mm, the solute feeding process was discontinued and the crystal was directionally solidified, giving rise to a composition profile as expected from the normal freezing process. This process has been demonstrated for the growth of homogeneous $\text{Ga}_{0.3}\text{In}_{0.7}\text{Sb}$ crystals [10.120].

Fig. 10.42 Elemental composition profile along the growth direction of the GaInSb graded seed crystal grown using periodic solute feeding process shown in Fig. 10.40

Another method for periodic solute feeding process is shown in Fig. 10.43. In this process, the higher-melting binary is used as the starting seed material for the ternary crystal growth. In Fig. 10.43, the process for GaInSb growth starting from GaSb seed is illustrated. The experiment starts with a GaSb single-

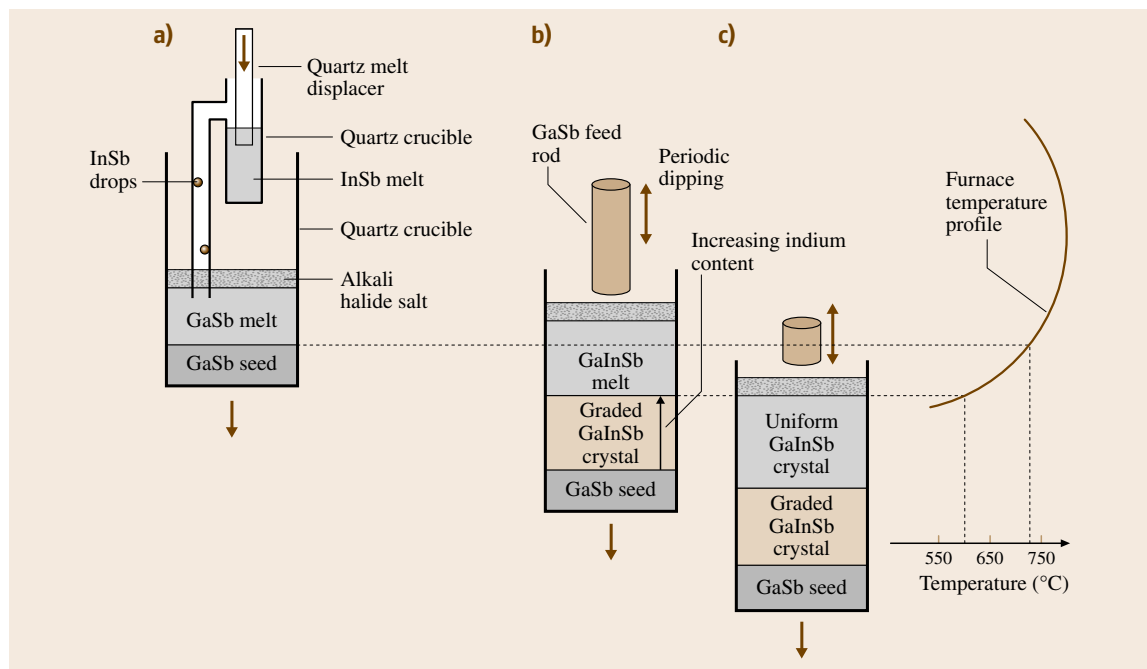

Fig. 10.43a–c Periodic solute feeding process for growth of graded-composition ternary seed and homogeneous ternary crystal in a single experiment by vertical Bridgman method

crystalline seed and a GaSb melt in the crucible. The lower-melting-point binary (InSb in this case) is present in a quartz melt displacer. After the furnace has been heated, the GaSb feed melts to form a melt–solid interface. The crucible is set for accelerated crucible rotation (ACRT) as in the previous case. By pressing the piston, the InSb can be periodically fed into the GaSb melt. After the initial InSb melt is dispensed into the growth melt to form GaInSb, the crucible is translated towards the lower-temperature zone of the furnace as in Bridgman growth. The graded-composition GaInSb ternary starts from the GaSb seed with increasing InSb content in the crystal. The InSb concentration in the melt increases with time as it is fed into the melt periodically. After the graded GaInSb seed growth, a GaSb feed is introduced into the melt periodically as in the previous case. The crucible translation is continued while the GaSb feed is periodically fed into the melt (Fig. 10.43c). This step results in a compositionally uniform GaInSb region as before (Fig. 10.40d). Care must be taken to ensure that the GaSb feed shown in Fig. 10.43b,c is introduced into the lower-temperature zone of the furnace without melting. The process illustrated in Fig. 10.43 can also be implemented by the gradient freezing process. In that case, the furnace temperature is decreased below the melting point of GaSb before it is introduced into the GaInSb melt for the homogeneous growth re-

Fig. 10.44 InSb mole fraction along the growth direction of GaInSb crystal grown using the first step of the process (feeding InSb) shown in Fig. 10.43

gion. Figure 10.44 shows the axial InSb mole fraction in a GaInSb crystal grown by the periodic InSb feeding process. The composition of the crystal was continuously varied from GaSb to InSb, showing the flexibility of the process for controlling the alloy concentration in the crystal.

The periodic solute feeding process described in this section can be universally applied for the growth of any ternary alloy system. The same experimental configurations that are being used for the respective binary growth can be used with the addition of the periodic solute feeding mechanism.

10.11 Role of Melt–Solid Interface Shapes

The melt–solid interface shape during crystal growth plays a significant role in the quality of the grown crystals [10.100, 122, 123]. As shown in Fig. 10.45, with

Fig. 10.45a–c Melt–solid interface shapes observed during vertical Bridgman growth: (a) convex, (b) planar, and (c) concave interface shapes

respect to the solid, the melt–solid interface shape could be (a) convex, (b) planar or (c) concave. The shape represents the isotherm corresponding to the melting point of the material [10.124]. A convex interface with respect to the solid is created when the temperature gradient at the growth interface is low since the heat extraction through the grown crystal becomes dominant, whereas the concave interface towards the melt is formed when the temperature gradient is large because heat is lost out through the crucible. The concave interface as shown means that the temperature at the center is higher than that around the edges. The arrows in the figure indicate the direction of heat flow, which is perpendicular to the melt–solid interface at every point. The curvature of the interface is dictated by the complex heat transfer between various components in the growth system (furnace, crucible, melt, crystal, encapsulant, gas, crucible holders, etc.). In general, a concave interface shape is the least desirable since it encourages polycrystalline

grains to originate from the walls of the crucible and grow into the crystal. The convex interface shape is desirable from the point of view of grain elimination (any polycrystalline grain will grow outwards to the edge of the crucible). However a convex interface tends to produce twinning in the crystal. Both concave and convex interfaces will produce nonuniform stress along the radial direction, thus producing a high dislocation density in localized regions across the wafer. The planar interface is the ideal for crystal growth. A significant amount of computational modeling and experimental research is being conducted to study the interface shape in real crystal growth configurations [10.125–127]. This is being done to identify thermal and growth conditions under which a planar melt–solid interface could be obtained.

The shape of the melt–solid interface determines the radial compositional profile in ternary crystals [10.100]. A planar interface is absolutely necessary for obtaining wafers with uniform alloy composition. Hence it is very important to understand the heat transfer processes during ternary crystal growth and identify suitable conditions that could lead to planar interface during growth. In general, for a Bridgman-type configuration, the primary heat flow mechanisms are: radiative heat transfer from the hot zone of furnace to the melt, convection and conduction in the melt, conduction in the solid (crystal) and radiative heat transfer from the crystal to the cold zone of the furnace [10.128]. Other effects such as latent heat release at the melt–solid interface, convective flow, etc. make secondary contributions. Convection in the liquid can be driven by several forces. In the presence of gravitational forces, the most importance source of convective flow is due to the density differences caused by temperature and composition differences in the liquid. Additional flow can be driven by the volume change accompanying the phase change. If free surfaces (i. e., liquid–vapor, liquid–liquid) are present, Marangoni convections due to the surface tension gradient originating from the difference of temperature and solute concentration occur. The density-driven convective flow due to the temperature difference can be prevented if the temperature increases with height (the stabilizing condition, as in the case of vertical Bridgman configuration) and no temperature gradient is present in the radial direction even in the presence of gravitational forces [10.96]. If a solute is present, the growth process will result in compositional differences ahead of the growth interface because the rejected solute from the crystal is lower or higher in density than the solvent; these composition differences may result in a thermoso-

lateral convective instability [10.96]. A global model incorporating the materials properties of all the components present in the growth chamber is necessary to predict the melt–solid interface shape to a high degree of accuracy. In this section, we will discuss the experimental parameters that alter the melt–solid interface curvature during ternary crystal growth using Bridgman or gradient freeze type methods.

During Bridgman growth of ternary crystals, the temperature gradient in the melt, at the melt–solid interface, and in the crystal plays a significant role in determining the curvature of the interface [10.121].

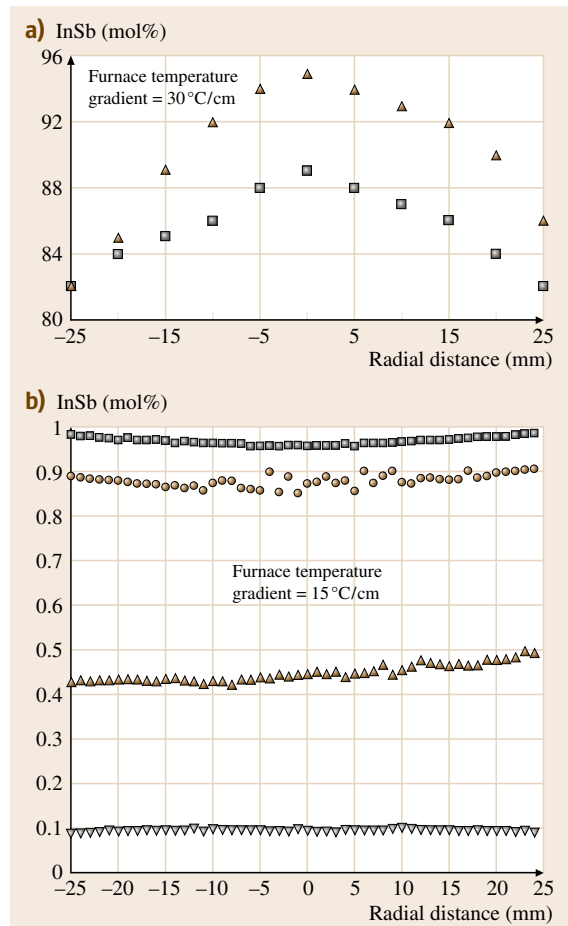

Fig. 10.46a,b Correlation of melt–solid (MS) interface shape with radial InSb composition profile in GaInSb crystals: **(a)** concave M–S interface resulting in convex InSb profile (Δ: without melt stirring, □: with melt stirring) and **(b)** planar M–S interfaces resulting in uniform InSb profiles (with melt stirring)

Fig. 10.47 Schematic diagram of vertical Bridgman growth configuration with submerged heater or baffle in the melt used for flattening the melt–solid interface shape

Interestingly, the effect of forced convection on the interface curvature seems to be weaker than the effect of temperature gradient. Figure 10.46 shows the radial InSb composition profiles for vertical Bridgman grown GaInSb crystals with furnace temperature gradients of 30 and 15 °C/cm. Under an axial temperature gradient of 30 °C/cm, the growth interface is highly concave with respect to the solid (leading to a convex InSb radial profile). Figure 10.46a also shows the radial InSb profile for a crystal grown using melt stirring (stationary stirrer in the melt with constant crucible rotation of 100rpm, as in Fig. 10.10a). The curved compositional profile clearly indicates that high axial gradients lead to curved interfaces which are very difficult to flatten even with strong fluid stirring. The convex radial profile is also seen in the crystal grown with ACRT (Fig. 10.27). This clearly demonstrates the strong influence of temperature gradient on the interface curvature. Higher temperature gradients are known to produce concave melt–solid interface shapes. Lowering the gradient would certainly flatten the interface. However very low gradients must be avoided since the probability of constitutional supercooling will be enhanced with low gradients. For ternary crystals with diameter of 50 mm, the optimum temperature gradient is in the

range of 10–15 °C/cm, wherein constitutional supercooling can be avoided by suitable melt stirring and a flat interface could be achieved. Figure 10.46b shows the radial InSb composition profiles in a GaInSb crystal grown with a temperature gradient of 15 °C/cm and with melt stirring using ACRT (Fig. 10.27). The interface curvature is extremely flat, except towards the end of growth where the interface curvature varies slightly. If melt stirring is not used under the same gradient of 15 °C/cm, constitutional supercooling was observed for growth rate of 0.7 mm/h or higher. Hence a combination of low temperature gradient and low growth rate or melt stirring is necessary to obtain a flat interface without constitutional supercooling [10.121].

A sophisticated method for achieving planar melt–solid interface shape during crystal growth is shown in Fig. 10.47 [10.86, 87]. In this configuration (the submerged heater method, SHM), a heater is enclosed inside a quartz disc-shaped hollow enclosure (baffle). A shallow growth melt is contained between the baffle and the growth interface. Heat is axially supplied to the melt by the disc-shaped heater submerged in the melt, which is held at a temperature higher than the melting point of the materials and is extracted downward through the crystal during the growth. This results in flattening of the melt–solid interface. It is also possible to use the submerged baffle without power. The thermal conductivity of the baffle on its own could flatten the interface without the addition of extra heat. This scheme enables the crystal to grow under steady-state conditions due to the low level of convection in the small melt zone and the continuous and stable replenishment of melt and impurities. While the crucible is lowered, the large melt above the baffle provides a liquid feed to the small melt enclosed between the crystal and the baffle. The downward flow in the gap between the crucible and the baffle inhibits back-diffusion, and buoyancy-driven convection is not expected since the top is hotter than the bottom in the small melt zone. The submerged baffle can also be rotated to create forced convection in the growth melt. This has been employed to eliminate cracks in GaInSb ternary crystals [10.25]. Advanced fluid flow patterns [10.129] will be necessary to achieve a high degree of compositional homogeneity in ternary crystals. In the future, a combination of ACRT [10.130–132], magnetic fields [10.133], and SHM [10.87] could enable the necessary heat and mass transport for growing compositionally tailored device-grade ternary crystals.

10.12 Conclusion

Ternary single-crystal substrates are important for advanced photonic, electronic, and photovoltaic-based power generation device structures. Large-scale crystal growth technology for growing reliable device-grade ternary substrates is still in its infancy and requires substantial engineering development. The Bridgman or gradient freezing process is the most suitable method for growing large-diameter III–V ternary bulk crystals. Ternary crystal growth requires low temperature gradient and low growth rate. Typical temperature gradient and growth rate are in the range of 5–15 °C/cm and 0.02–0.5 mm/h, respectively. A low temperature gradient helps to ensure a planar melt–solid interface shape, which is necessary for a uniform radial composition in the crystal as well as reducing the strain level in the crystal to avoid cracking. Low growth rates are necessary to avoid constitutional supercooling and interface breakdown, which lead to transition from single- to polycrystal growth and the generation of microcracks. Melt stirring using forced

convection is crucial to avoid constitutional supercooling during growth. Stirring also helps in enhancing crystal growth rate. Special conditions are necessary for ternary single-crystal seed generation. The rate of compositional grading along the crystal during the seed generation process should be maintained below a specific level in order to avoid strain-gradient-related cracks in the crystal. Precise melt composition control using solute replenishment is absolutely essential for the growth of compositionally homogeneous crystals. In this chapter, an advanced crystal growth process has been described that could lead to growth of high-quality device-grade and commercially viable ternary substrates. The proof of concept for the process has been successfully demonstrated by laboratory-scale large-diameter crystal growth experiments. It is anticipated that the single-step process for seed generation and homogeneous crystal growth could be universally employed for all III–V ternary compounds.

11. Growth and Characterization of Antimony-Based Narrow-Bandgap III–V Semiconductor Crystals for Infrared Detector Applications

Vijay K. Dixit, Handady L. Bhat

Materials for the generation and detection of 7–12 μm wavelength radiation continue to be of considerable interest for many applications such as night vision, medical imaging, sensitive pollution gas monitoring, etc. For such applications HgCdTe has been the main material of choice in the past. However, HgCdTe lacks stability and uniformity over a large area, and only works under cryogenic conditions. Because of these problems, antimony-based III–V materials have been considered as alternatives. Consequently, there has been a tremendous growth in research activity on InSb-based systems. In fact, InSb-based compounds have proved to be interesting materials for both basic and applied research. This chapter presents a comprehensive account of research carried out so far. It explores the materials aspects of indium antimonide (InSb), indium bismuth antimonide ($\text{InBi}_x\text{Sb}_{1-x}$), indium arsenic antimonide ($\text{InAs}_x\text{Sb}_{1-x}$), and indium bismuth arsenic antimonide ($\text{InBi}_x\text{As}_y\text{Sb}_{1-x-y}$) in terms of crystal growth in bulk and epitaxial forms and interesting device feasibility. The limiting single-phase composition of $\text{InAs}_x\text{Sb}_{1-x}$ and $\text{InBi}_x\text{Sb}_{1-x}$ using near-equilibrium technique has been also addressed. An overview of the structural, transport, optical, and device-related properties is presented. Some of the current areas of research and development have been critically reviewed and their significance for both understanding the basic physics as well as device applications are discussed. These include the role of defects and impurity on structural, optical, and electrical properties of the materials.

Tremendous efforts have been applied in the development of infrared (IR) detectors and sensor materials. Much of the research on IR optoelectronic has been focused mostly on military needs, with particular emphasis on the development of high-performance detectors operating in the 3–5 and 7–12 μm wavelength bands. In recent years civilian needs have become more dominant due to the development of IR light-emitting diodes (LED) and lasers, which provide low-cost sensitive pollution monitoring systems that detect trace gases by their fundamental vibrational–rotational absorption bonds [11.1]. Other applications include fire-fighting, environmental monitoring, fiber-optic and free-space optical communication systems, landfill gas monitoring, fuel-gas analysis, personal safety, sports, medicine, and a variety of horticultural uses that include total organic carbon dioxide measurement. For all these applications HgCdTe (MCT) has been the main material of choice in the past, but it has proved to be a difficult compound to prepare due to the high vapor pressure of Hg and weak Hg bond. Also its material parameters change with time, resulting in poor mechanical and thermal properties [11.2]. Because of these problems associated with MCT, antimony (Sb)-based III–V materials have been considered as more attractive alternatives. Also they have stronger covalent bonds between indium (In) and Sb, which makes them stable compounds. In particular, InSb-based materials such as $\text{InAs}_x\text{Sb}_{1-x}$, $\text{InBi}_x\text{Sb}_{1-x}$, and $\text{InBi}_x\text{As}_y\text{Sb}_{1-x-y}$ have been extensively explored for many years [11.2–12]. In this chapter, we will review mostly the investigations carried out on these materials for the past two decades. The review highlights the current status of understanding of the crystal growth process and various physical properties of InSb, $\text{InBi}_x\text{Sb}_{1-x}$, $\text{InAs}_x\text{Sb}_{1-x}$, and $\text{InBi}_x\text{As}_y\text{Sb}_{1-x-y}$. While InSb continues to be grown commercially, very few reports are available on the growth of large-sized crystals and wafers with high quality. Some recent studies have surely led to better understanding of the problems associated with the enhancement of the size and quality of the grown crystals.

Substantial bowing in the energy gap to values below those of InSb (0.17 eV) and InAs (0.38 eV) occurs in indium arsenic antimonide. The energy gap of $\text{InAs}_x\text{Sb}_{1-x}$ continuously decreases with increasing x and attains a minimum value of 0.1 eV for $x = 0.4$, at room temperature [11.13–19]. Further-

more, the very low effective mass of $\text{InAs}_x\text{Sb}_{1-x}$ across the compositional range raises the prospect of using this material extensively for detector applications. Although the benefits of alloying As in InSb were discovered more than 34 years ago and have been studied since then, all studies have been carried out on bulk samples made from crudely prepared polycrystals [11.19, 20]. The main growth limitations in $\text{InAs}_x\text{Sb}_{1-x}$ arise from the wide separation between the liquidus and solidus curves in the temperature–composition phase diagram and the very low diffusion rates in the solid phase. Hence most bulk crystal growth (near equilibrium) has been carried out using gradient freeze and zone recrystallization and with long annealing duration, usually resulting in polycrystals.

$\text{InBi}_x\text{Sb}_{1-x}$ is a very interesting material because it is composed of the semimetal InBi and the semiconductor InSb and hence the bandgap energy and lattice constant can be varied over a wide range. Consequently, these crystals are also useful for the applications mentioned above. However, this alloy is even more difficult to grow in single-crystal form because of the wide separation between the liquidus and solidus lines in its phase diagram. This leads to constitutional supercooling in the solution below the growth interface. Hence, the composition ratio in the grown crystals will not be the same as that in the solution. Recently Dixit et al. [11.9, 12] reported successful growth of $\text{InAs}_x\text{Sb}_{1-x}$ and $\text{InBi}_x\text{Sb}_{1-x}$ single crystals using the rotatory Bridgman method (RBM). Efforts are also being made for possible integration of these materials onto suitable semi-insulating and IR-transparent substrates. CdTe is the only semi-insulating and lattice-matched substrate available for this purpose, but it is very difficult to prevent In_2Te_3 precipitate formation at the interface during growth [11.21, 22]. Hence, Si, GaAs, and InP have been used as substrates for epitaxial growth of these materials [11.23–25]. In spite of the large lattice mismatch between GaAs and these materials, there are many reports on the growth of these heterostructures using molecular-beam epitaxy (MBE) [11.26, 27], metalorganic vapor-phase epitaxy (MOVPE) [11.28–32], liquid-phase epitaxy (LPE) [11.5, 10, 33–35], and melt epitaxy (ME) [11.36–38]. The lattice-mismatched heteroepitaxy affects the structural, optical, and electrical properties of these materials and these issues have been addressed in this review.

11.1 Importance of Antimony-Based Semiconductors

After silicon, germanium, and gallium arsenide, indium antimonide is perhaps the most studied semiconductor. This is because it has the smallest energy gap (0.17 eV) among the III–V binary semiconductors. InSb has a strong band nonparabolicity, a very large g factor and is intrinsic at room temperature [11.40–50]. Due to these intrinsic properties, its physics is qualitatively different from that of other common semiconductors. The ease with which quantum phenomena can be seen and cleanly modeled has for a long time made it a favorite of semiconductor researchers. Two material-specific parameters that define the utility of a possible device are the energy gap and the effective mass. These can be tuned by strained epitaxy to some extent. However, alloying of two or more semiconductors drastically widens the available parameter space of various physical properties. Most physical properties (energy gap, effective mass, and lattice constant) of the alloy are continuous functions of the alloy composition and interpolate between the end members as a polynomial of low order. The energy gap of InSb, although the smallest among the III–V binaries, is not small enough to be used in practical long-wavelength infrared detectors. Hence the material has to be engineered so that its gap is within one of the wavelength windows where the atmospheric gases are transparent, i.e., 3–5 and 7–12 μm . The desired gap tailoring can be accomplished by alloying with low-bandgap semiconductors or semimetal.

InSb–InAs is one of the interesting alloy of this class because the substitution of a fraction of antimony sites in InSb with isovalent arsenic reduces the energy gap to a value lower than the energy gap of either of the parent compounds; it consequently has the lowest energy gap among the III–V semiconductors. This system also has one of the largest bowing parameters among the semiconductor alloys (Fig. 11.1a) [11.13]. Therefore the effects of alloy disorder in determining the physical properties may be expected to be more significant. By alloying with a suitable fraction of InAs, a room-temperature energy gap in both atmospheric wavelength windows can be achieved.

The desired energy gap tailoring can be accomplished by alloying with InBi also (Fig. 11.1b). Since Bi is much larger than Sb it produces rapid reduction of the bandgap of InSb at the rate of 36 meV/%Bi [11.51–54]. Incorporation of Bi in InAsSb produces an even larger reduction in bandgap (55 meV/%Bi) as determined by absorption and photoluminescence studies. *Ma*

et al. [11.54] reported Bi incorporation in $\text{InAs}_x\text{Sb}_{1-x}$ lattice and decrease in the bandgap energy of MOVPE-grown epilayer. The high quality of these layers was evidenced by the production of photoluminescence. Huang et al. [11.51] calculated the expected bandgap energies for the $\text{InBi}_x\text{As}_y\text{Sb}_{1-x-y}$ alloys having the optimum Bi concentration by linearly interpolating the values of dE_g/dx between InAs and InSb, yielding $dE_g/dx = -55 \pm 19x$ (meV/%Bi). The variation of the energy gap with alloy composition manifests in the optical and electrical properties of respective materials.

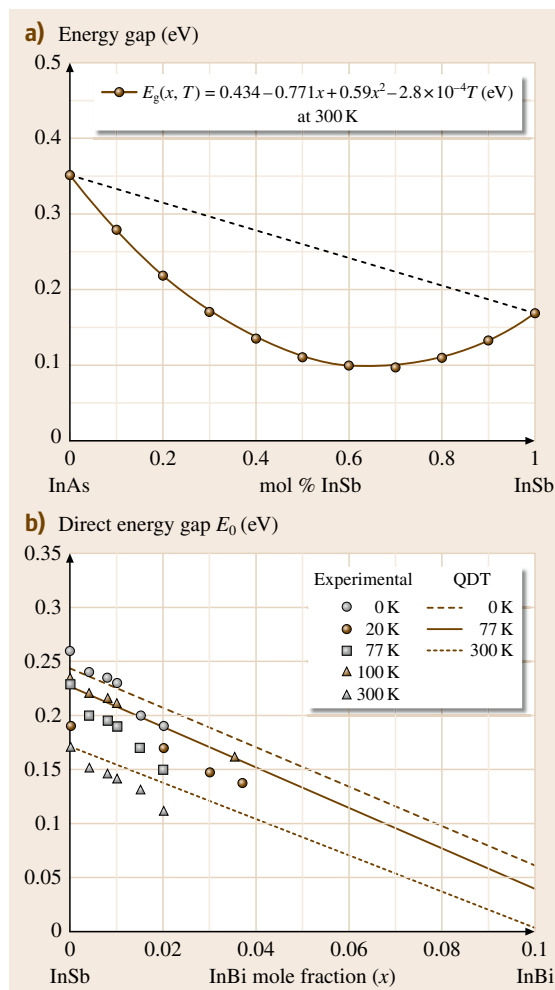

Fig. 11.1a,b Energy gap bowing for (a) $\text{InAs}_x\text{Sb}_{1-x}$, and (b) $\text{InBi}_x\text{Sb}_{1-x}$ (after [11.13, 39])

11.2 Phase Diagrams

In order to grow homogeneous and stoichiometric bulk and epitaxial single crystals of binaries and ternaries it is essential to understand the phase diagrams of these materials. The phase diagram of InSb, $\text{InAs}_x\text{Sb}_{1-x}$, and $\text{InBi}_x\text{Sb}_{1-x}$ are briefly described below.

11.2.1 InSb

The phase diagram of InSb was determined by *Liu and Peretti* [11.56] and is reproduced in Fig. 11.2a. It is characterized by the presence of two eutectics occurring at 0.8 and 68.2 at. % Sb. From the diagram it is clear that at the extreme left there exists a phase consisting of pure In (α -phase) with a melting point of 156°C. At the extreme right is elemental Sb (γ -phase) with a melting point of 630°C. InSb has a congruent melting temperature below the melting point of one of its constituents. This leads to certain differences between solution growth and congruent melt growth in terms of composition of In and Sb. Of interest in the phase diagram is the β -phase in the indium–antimony system, which has a congruent melting temperature of 525°C. The transition from solid to liquid phase occurs at composition of 50 at. %. This is the point where the crystal is grown stoichiometrically. Alloys with a deviation as small as 0.5% from the stoichiometric ratio show phase separation, making the phase very sensitive to composition. The β -phase divides the diagram into

two subsystems, namely the In–InSb (the $\alpha + \beta$ -phase) and the InSb–Sb (the $\beta + \gamma$ -phase) alloys. Also represented are the $L + \alpha$ - and the $L + \gamma$ -phases. Above the curve, InSb is in the liquid phase. For the growth of InSb epilayers using LPE, In–InSb region is preferred over other region, because In has a lower vapor pressure compared with Sb.

11.2.2 $\text{InAs}_x\text{Sb}_{1-x}$

Shih and Peretti [11.55] investigated the phase diagram of the InAs–InSb system and obtained a degenerate eutectic diagram with the terminal solid solution with 2% InSb. *Goryunova and Fedorova* [11.58] also reported

Fig. 11.2a–d Equilibrium phase diagrams of (a) InSb, (b) InSb–InAs, and (c) InSb–InBi (after [11.55–57])

Fig. 11.2 (d) Equilibrium phase diagrams of $\text{InBi}_x\text{Sb}_{1-x}$ at 300 K (after [11.62])

investigation on the same system with a maximum terminal solid solution with $\approx 3\%$ InSb, which was in reasonable agreement with the result of *Shih* and *Peretti* [11.55]. Later, *Woolley* et al. [11.59] showed the complete solid solution for all compositions. *Stringfellow* and *Greene* [11.60] also reported the full phase diagram of $\text{InAs}_x\text{Sb}_{1-x}$. The analysis was carried out using x-ray and differential thermal analysis. They made $\text{InAs}_x\text{Sb}_{1-x}$ polycrystalline samples for the complete range of composition and annealed them at 525°C for 3 months. Alloys over a considerable range of composition were approaching a single-phase state, but alloys in the approximate range of 90–40 mol % InAs showed an apparent two-phase equilibrium condition when investigated by x-ray methods. When alloys of the same composition were first annealed to single phase at 550°C followed by annealing at 525°C for approximately 3 months, no indication of any splitting into a two-phase condition could be observed by x-ray investigation. The complete phase diagram for

all composition is shown in Fig. 11.2b. It would thus appear that at these compositions the diffusion rates in the solid are so low that, even at temperatures only $\approx 50^\circ\text{C}$ below the solidus, equilibrium cannot be attained under normal practical conditions, and the form of the equilibrium diagram at temperature below 550°C cannot be determined. *Dutta* and *Miller* [11.61] also reported studies on the phase diagram of this material.

11.2.3 $\text{InBi}_x\text{Sb}_{1-x}$

The phase diagram of $\text{InBi}_x\text{Sb}_{1-x}$ was determined by *Joukoff* and *Jean-Louis* [11.63] using differential thermal analysis (DTA) only up to 6 at. % Bi. They found that the maximum equilibrium solubility limit of Bi was 2.6 at. % in InSb, but *Zilko* and *Greene* [11.57] reported that in metastable conditions the solubility of Bi in InSb is 12 at. %. As can be seen from Fig. 11.2c wide separation exists between the liquidus and solidus lines in the phase diagram, which leads to constitutional supercooling in the solution below the growth interface. Hence, the composition ratio in the grown crystals will not be same as that in the solution. Two metastable phase boundaries T_{M1} and T_{M2} are also shown in Fig. 11.2c. Below the T_{M1} phase boundary InBi–InSb forms one single stable $\text{InBi}_x\text{Sb}_{1-x}$ phase, while in the region between the two-phase boundaries (T_{M1} and T_{M2}) the solution forms stable $\text{InBi}_x\text{Sb}_{1-x}$ and Bi phase. In the region above T_{M2} the solution forms stable $\text{InBi}_x\text{Sb}_{1-x}$, InBi, and Bi phases. Very recently *Minic* et al. [11.62] reported thermodynamic predictions for the equilibria of the InSbBi system. They estimated the phase diagram at 300°C and compared it with experimental results obtained by scanning electron microscopy (SEM) analysis (Fig. 11.2d). They experimentally determined that liquid and rhombohedral phases of $\text{In}_{0.31}\text{Sb}_{0.38}\text{Sn}_{0.31}$ sample contained higher contents of bismuth compared with the prediction, which suggests the need for the introduction of ternary interaction parameters for the calculation.

11.3 Crystal Structure and Bonding

For understanding the optical and electrical properties of InSb, $\text{InAs}_x\text{Sb}_{1-x}$, and $\text{InBi}_x\text{Sb}_{1-x}$ crystals it is essential to understand the crystal structures and bonding of these materials, which are briefly described below.

11.3.1 Crystal Structure and Bonding of InSb

The structure of InSb was first determined by *Goldschmidt* [11.43] and later in detail by *Iandelli* [11.64] using conventional x-ray structure determination tech-

Fig. 11.3 Lattice parameter variation of InAsSb with composition (after [11.5, 20])

niques and found to be of zincblende type. The space group of InSb is $F\bar{4}3m$ [11.43] and hence it belongs to the point group $\bar{4}3m$. In the structure, each In atom is coordinated to four Sb atoms and vice versa. The presence of dissimilar atoms in the lattice imparts a directional character to the lattice. Hence, the direction from the In to the Sb is not equivalent to that from Sb to In. Thus, due to the lack of center of symmetry, the 111 direction forms the polar axis and there is a distinction between the [111] and the $\bar{1}\bar{1}\bar{1}$ directions. Conventionally, the direction from group III to V atom is $\bar{1}\bar{1}\bar{1}$ and from group V to III atom is [111]. In the zincblende structure, the crystal viewed perpendicular to [111] direction appears as sheets of alternate group III and V atoms stacked over one another. Dewald [11.65], while studying the growth of oxide layers on InSb, noticed a difference in the growth kinetics of (111) and $(\bar{1}\bar{1}\bar{1})$ surfaces. This difference in the behavior of the two surfaces was also noticed by other workers [11.66] during the observation of etch pits on InSb using CP4 ($\text{HF} : \text{HNO}_3 : \text{CH}_3\text{COOH} : \text{H}_2\text{O} = 3 : 5 : 3 : 20$) etchant. For example, it has been shown that dislocation etch pits appear on $(\bar{1}\bar{1}\bar{1})$ and not on (111) face. Also, growth of InSb crystals is easier on $(\bar{1}\bar{1}\bar{1})$ face than on (111) face. The bonding between In and Sb is a combination of two idealized states (purely ionic and

purely covalent states) as represented by the equation below

$$\Phi = a_{\text{ionic}}\Phi_{\text{ionic}} + a_{\text{covalent}}\Phi_{\text{covalent}} \quad (11.1)$$

This means that the bonding is of mixed nature and is characterized by the ionicity, which is the ratio of a_{ionic} to a_{covalent} [11.68]. This lends a mixed character to the lattice, giving rise to a net polarity along certain directions.

11.3.2 Structural Properties of $\text{InAs}_x\text{Sb}_{1-x}$

There are not many reports on the structural properties of $\text{InAs}_x\text{Sb}_{1-x}$ except for a study on the variation of lattice parameter with composition [11.20]. The variation of lattice parameter with composition is shown in Fig. 11.3. The experimental curve (solid line) obtained by Woolley and Warner [11.20] for the whole compositional range (in polycrystalline samples) crosses Vegard's line at approximately 67 mol % InAs, indicating that Vegard's law is not satisfied except at one point ($x = 0.67$). Recently Dixit et al. [11.5, 69] also reported similar observation up to 12% As. Their results are shown in the inset of Fig. 11.3. The maximum difference in the lattice parameters (6.330 Å) obtained from experimental curve (from Woolley and Warner's work) and the Vegard line is 0.030 Å at 33% InSb.

Fig. 11.4 Relative change of lattice parameter of InBiSb for Bi in (1) antimony position, (2) interstitial position, and (3) indium position, and (4) experimental curve (after [11.67])

11.3.3 Crystal Chemical Aspect of Bi Substitution in InSb

A large region of the phase diagram of $\text{InBi}_x\text{Sb}_{1-x}$ system corresponds to the region of primary crystallization of solid solutions based on InSb. Since In forms two stable compounds with Bi, depending on the composition and temperature of the molten solution, Bi can occur in three basic forms, Bi, InBi, and In_2Bi , in the melt [11.66]. By varying the crystallization conditions, one can follow how various forms of Bi in the melt influence its solubility in InSb as well as structural properties of $\text{InBi}_x\text{Sb}_{1-x}$. The character of Bi in the crystal lattice of InSb was determined by comparing the exper-

imental composition dependence of the lattice parameter a with that calculated theoretically for substitutional and interstitial solid solutions and also by studying the spectra of diffuse scattering of x-rays. The values of a were measured with a precision of $\pm 5 \times 10^{-5} \text{ \AA}$ [11.70]. By comparing the theoretical and experimental composition dependences of the relative change in the lattice parameters of $\text{InBi}_x\text{Sb}_{1-x}$, one can determine the position of Bi in InSb, as shown in Fig. 11.4. The results indicate that, when the relative change in the lattice parameter with Bi composition is large, Bi goes into interstitial position, whereas when it is small Bi goes into In position. For moderate change in the lattice parameter with Bi composition, Bi goes into Sb position.

11.4 Material Synthesis and Purification

Since the discovery of InSb material, considerable attention has been devoted to its growth in single-crystal form [11.71–75]. Growth of good-quality InSb single crystal depends on the purity of the source materials and homogeneous synthesis of the starting materials. InSb is synthesized by taking stoichiometric amounts of In and Sb in a quartz ampoule, kept in an atmosphere of pure argon or hydrogen. The charge is melted and mixed in the molten state inside the quartz ampoule and stirred either mechanically or electromagnetically. Synthesized InSb carries impurities either from the source materials or from growth environment. Use of high-purity source materials helps to avoid severe contamination of the synthesized compound. For purification of InSb two important techniques have been used, viz. volatilization and zone refining.

11.4.1 Volatilization

In volatilization, the melt is kept at an elevated temperature for very long periods, so that impurities that have higher volatility evaporate out of the melt. In InSb, cadmium (Cd), an elemental acceptor impurity, is effectively removed by volatilization. In the case of InSb, antimony has a higher vapor pressure compared with In. Hence, Sb escapes from the charge during volatilization. Therefore, whenever this process is adopted, Sb is taken in excess to compensate for its escape from the melt during volatilization.

11.4.2 Zone Refining

In zone refining (a technique developed by *Pfann* [11.76]), purification takes place because of the impurity atom's preference to stay either in the molten zone or in the solid zone (depending on the value of a segregation coefficient) as it moves along the ingot. This preference for the impurity is measured by defining an equilibrium distribution coefficient, k_{eq} , given by C_s/C_l , the ratio of the concentration of the impurity in the solid and liquid phases. The larger the deviation of k from 1, the easier it is to remove the impurity through zone refining. *Harman* [11.77] carried out extensive experiments on zone refining of InSb and found two main impurities, viz. Zn and Te, that segregated from the ingot. While Zn had an acceptor-like characteristic in InSb, Te showed donor-like properties. *Strauss* [11.78] determined the distribution coefficients of various elements such as Cd, Zn, Se, and Te in InSb. Zinc has a k_{eff} of 2.3–3.5 in InSb, which makes it fairly easy to be zone refined, whereas Te has a k_{eff} of 1 in InSb, which makes it almost impossible to remove from InSb. One can use the relation $c(x) = k_{\text{eff}}c_0(1 - g)^{k_{\text{eff}}} - 1$ to find the concentration at any location (x) of the growth front in different conditions, where g is the fraction of crystallized material and c_0 is the initial concentration. Here it is assumed that k_{eff} does not vary with concentration or temperature. Recent studies show that k_{eff} depends on growth rate also. Hence, k^* may in principle differ from k_{eff} and may depend on the growth rate, interface orientation, and solute concentration. Hence it is more

appropriate to use the following equation

$$k_{\text{eff}} = \frac{k^*}{k^* + (1 - k^*) \exp\left(\frac{-f\delta}{D}\right)}, \quad (11.2)$$

where f is the growth rate, δ is the diffusion thickness ($\delta = 1.6D^{1/3}\nu^{1/6}\omega^{-1/2}$), which is a function of rotation rate ω , the viscosity of the liquid ν , and the diffusion coefficient D of the impurity in the liquid. Under conditions of stirring at the interface, k^* is close to k_{eff} , but the two are quite different in real experimental situations. In fact, for certain impurities, very strong dependence of k^* on the crystallographic direction of ingot to be refined has been noticed, as is the case for Te in InSb. This anisotropic segregation created many difficulties for Te removal. It was thus difficult to remove Te ef-

fectively, as it always depended on ingot orientation and the ingots used were usually polycrystalline. However, the observation of the dependence of k^* on ingot orientation by Mullin and Hulme [11.79] showed that k^* is about 0.5 in the off-[111] direction and this can be effectively used to segregate Te from InSb ingots whose axis is crystallographically inclined away from [111] direction. In fact, k^* was not found to vary much on facets other than (111). Thus, researchers began to use off-[111] ingots for the refining process. Hence, the anisotropic segregation of Te in InSb, which posed problems earlier, was cleverly used to advantage in the refining process. However, this necessitated the use of oriented InSb ingots for the refining process rather than polycrystalline ingots as previously sought.

11.5 Bulk Growth of InSb

Since the discovery of InSb a large number of workers have performed growth experiments on InSb using a variety of techniques. Prominent examples are briefly described here.

11.5.1 Zone Melting

In the early stages, the growth technique used in the case of InSb was predominantly *zone melting* so that the refining and the growth could be carried out together. It was often found that multiple refining passes led to single-crystal growth. Mueller and Jacobson [11.80] used seeds of orientations [110], [111], and [211] to grow single crystals. Coherent twins were seen to occur, with the twin boundaries parallel to {111} planes. It was also observed that twinning occurred more readily when an [111] A surface was exposed to the melt. Superior growth characteristics of [111] B direction as compared with [111] A were demonstrated [11.81].

11.5.2 Vertical and Horizontal Bridgman Methods

Parker et al. [11.82] reported the growth of InSb single crystals by the horizontal Bridgman technique. Single crystals grown after refining had an etch pit density (EPD) of 10^5 cm^{-2} with carrier mobility of $919000 \text{ cm}^2/(\text{V s})$ (at 80 K). InSb was also grown by vertical Bridgman technique in quartz crucibles to yield single crystals with mobilities on the order of $10^4 \text{ cm}^2/(\text{V s})$ [11.71]. Bagai et al. [11.72] used semi-circular heaters to refine and grow single crystals with

high mobility by horizontal Bridgman technique. Although the growth of InSb has been tried by a variety of methods, and single crystals have been obtained, various problems continue to plague its production. The origin of most defects is traced to the growth environment, particularly the temperature. Impurity striation which was a common problem in Czochralski (CZ) grown InSb was also encountered in the Bridgman configuration. Zhou et al. [11.83] applied accelerated crucible rotation technique (ACRT) to the directional solidification of Te:InSb in a Bridgman system with a view to reduce rotational striation. Alternate methods such as the application of magnetic field during growth have also been attempted to tackle this problem [11.84, 85]. The magnetic field is known to reduce temperature fluctuations by damping convection in the melt. Better axial homogeneity in Te:InSb was observed by growth in a magnetic field. In the last decade great strides have been made in rheology and temperature modeling during growth to map the exact thermal environment in the growth chamber. Such studies have yielded a variety of information that provides greater insight into the growth phenomena. In situ observation of the growth of InSb by Bridgman method [11.86] has shown considerable supercooling during growth. This raises serious doubts as to whether the growth of the crystal under such a situation is from a homogeneous melt, a condition essential for growth. There has been a lot of work to understand the role that the crystal-melt interface plays during growth. Growth constrained by the crucible, such as in Bridgman technique, has been modeled [11.87–89], and the role that the ther-

mal properties of the melt and solid play in growth and interface shapes has been studied. A variety of quenching and etching techniques [11.90] have been developed to mark the growth history. Such experiments help researchers to study the origin of defects such as striation and coring, which lead to crystal inhomogeneity. Feedback from such studies helps to improve growth conditions. *Campbell and Koster et al.* [11.91] studied interface visualization through radiographic technique and calibrated interface temperature measurements to study growth of InSb from off-stoichiometric melts. Recently sequential-freeze technology has further been used for the study of segregation [11.92, 93]. This system has been used to test the effects of microgravity [11.94, 95] on growth. Large-sized InSb wafers are being produced (up to 100 mm diameter) in cutting-edge commercial product by Firebird Technology [11.96].

Czochralski Growth

Parker et al. also reported the growth of InSb by the CZ technique [11.82]. Polycrystalline zone-refined feed

material was used as the starting charge for growth. In fact, crystals grown by CZ from zone-refined ingots as the starting material gave the best results, yielding an EPD as low as 500 cm^{-2} . *Allred and Bate* [11.97] grew single-crystal InSb by CZ technique along $\langle 111 \rangle$ and $\langle 110 \rangle$ directions. They used radioactive Se and Te as dopants to trace dopant homogeneity in the pulled crystals. It was observed through contact radiography that the dopant formed a central core in the crystal where it was incorporated in large amounts, termed the coring effect. This was seen particularly for crystals grown along $\langle 111 \rangle$ directions. When grown along directions such as $\langle 110 \rangle$, it was seen that the dopant was preferentially incorporated in the $\{111\}$ facets that occurred at the edges of $\langle 110 \rangle$ boules. *Terashima* [11.98] introduced InN in InSb melt during the CZ growth to improve the crystals in terms of EPD. This was proposed to be the effect of nitrogen doping of the melt via InN. *Hurle et al.* [11.99] performed growth experiments of InSb from off-stoichiometric solutions which were either In or Sb rich. There exist many reports on the growth of InSb crystals using Czochralski method and the formation of various types of defects [11.97–102].

Traveling Heater Method (THM)

Benz and Müller [11.103] conducted various experiments on growth of InSb by the traveling heater method. The THM is a solvent method, and inclusion of the solvent from the feed is common in crystals grown by this method. Both vertical and horizontal configurations have been used and have obtained single crystals with no inclusion. The defect densities in the grown crystals were evaluated to be about 1000 cm^{-2} . The optimized growth rate for the growth of inclusion-free crystals was about 2.5 mm/day. It was found that higher growth rates led to solvent inclusions. The results were similar in the horizontal case. *Hamaker and White* [11.104] used the temperature gradient zone melting (TGZM) technique to study the growth kinetics in InSb. Thus InSb bulk crystals can be grown by many techniques, but at present the economical and large-sized crystals are produced by Bridgman methods. Also at present there is no incentive to use more sophisticated technique for growth of InSb. Some crystals grown in the authors' laboratory are shown in Fig. 11.5 [11.11, 69, 105, 106].

11.5.3 Bulk Growth of $\text{InAs}_x\text{Sb}_{1-x}$

Woolley and Warner [11.20] have reported two methods for the preparation of $\text{InAs}_x\text{Sb}_{1-x}$ alloys, viz. slow directional freezing and slow zone recrystallization of

Fig. 11.5 InSb crystals and wafers of different sizes

suitable ingots. All the ingots were produced by melting together appropriate amounts of high-purity InAs and InSb. In slow directional freezing, ingots were prepared using equimolar proportions of InSb and InAs. Initially a furnace with a temperature gradient of 10 K/cm was used and temperature was controlled by an on-off controller, so that the time required to freeze the ingot completely was $\approx 2\text{--}3$ months. It was found that each end of the ingot was in good single-phase condition and the composition varied from 3 mol % to 12 mol % of InSb at one end and 88 mol % to 98 mol % at the other end. In between these regions however there was some 3 cm of the ingot where there was a very rapid change in composition with position and

where the material was not in equilibrium condition. An alternate method for preparing ingots of $\text{InAs}_x\text{Sb}_{1-x}$ alloys is the zone recrystallization technique. Here larger temperature gradients are used so that constitutional supercooling could be less of a problem, and the rate of movement of the freezing surface is directly controlled by the movement of the heater. *Glazov and Poyarkov* [11.107] reported homogeneous growth of this material in thin-foil form using rapid quenching. Recently *Dixit et al.* [11.9] reported growth of bulk single crystals of $\text{InAs}_x\text{Sb}_{1-x}$ for $0 \leq x \leq 0.05$ using RBM (Fig. 11.6). The phase diagram of In–As–Sb, which has been well studied both theoretically and experimentally [11.55, 61], was used to determine the

Fig. 11.6 (c) Schematic of RBM growth apparatus: (a – Antivibration mount, b – wheels, c – guided coupler, d – platform, e – aluminum frame, f – threaded lead screw, g – ball bearing, h – Wilson seal, i – quartz tube, j – ampoule, k – furnace, l – universal coupler, m – motor M_1 , and n – geared motor M_2). initial reaction temperatures; these were in the range of 600–700 °C for various compositions in their experiments. $\text{InAs}_x\text{Sb}_{1-x}$ was synthesized by diffusing arsenic into high-purity InSb. Although various molar proportions, viz. $\text{InSb} : \text{As} = 95 : 5, 90 : 10, 85 : 15, 80 : 20$, and $75 : 25$, were tried, it was found that homogeneous single crystals of $\text{InAs}_x\text{Sb}_{1-x}$ could be grown only up to starting proportion of 90 : 10, beyond which the grown crystals were inhomogeneous and often phase separated. It was observed experimentally that the liquid–solid interface was slightly concave and symmetric with respect to ampoule axis. Typical size of the grown crystals was 8 mm diameter and about 45 mm length. The ingots were single crystalline up to ≈ 35 mm, after which they were multigrain. Wafers were made from the 10–20 mm region from the tip of the ingot. Figure 11.7a shows a typical crystal and wafers. If extensive work is carried out in these directions, bulk growth of $\text{InAs}_x\text{Sb}_{1-x}$ leading to large-size device-quality wafers can be achieved.

11.5.4 Bulk Growth of $\text{InBi}_x\text{Sb}_{1-x}$

Compared with $\text{InAs}_x\text{Sb}_{1-x}$ it is even more difficult to synthesize and grow single crystals of $\text{InBi}_x\text{Sb}_{1-x}$. The first work on synthesis and growth of $\text{InBi}_x\text{Sb}_{1-x}$ was reported by Jean-Louis et al. [11.108], followed by Joukoff and Jean-Louis [11.63]. The growth was

carried out using Czochralski technique, using $\langle 111 \rangle$ -oriented InSb seed rods of 3 mm diameter. Single crystal of $\text{InBi}_x\text{Sb}_{1-x}$ could be obtained from a melt up to 30% InBi, which yielded $x = 0.001$, insufficient for development of detectors in the 8–12 μm atmospheric window. Hence they attempted growth with 70% InBi melt, which did not give single crystal. In the intermediate range of 50–60 % they could obtain single crystal up to $x = 0.026$. Later, in 1991, Ozawa et al. [11.109] reported growth of $\text{InBi}_x\text{Sb}_{1-x}$ using RBM. They could grow $\text{InBi}_x\text{Sb}_{1-x}$ single crystals with x varying from 0.016 to 0.03 from the seed region to the end of the ingot. This indicated that the segregation coefficient of Bi in InSb was less than unity. They could enhance the Bi content up to ≈ 5 at. % by codoping with gallium [11.110]. Dixit et al. [11.12] also reported growth of bulk single crystals of $\text{InBi}_x\text{Sb}_{1-x}$ with $x = 0.067$ using RBM. $\text{InBi}_x\text{Sb}_{1-x}$ was synthesized using various molar proportions (1 : 1, 1 : 3, 1 : 4, and 1 : 5) of InSb and InBi. It was found that, compared with 1 : 1 and 1 : 3, 1 : 4 yielded higher Bi concentration in $\text{InBi}_x\text{Sb}_{1-x}$ crystal as well as better homogeneity. However further increase of InBi molar ratio to 1 : 5 led to formation of InBi and In_2Bi precipitates. Similar compositional ratio (1 : 4) was also employed by Kumagawa et al. [11.110]. Typical size of the grown crystals are 8 mm diameter and about 25 mm length. Figure 11.7b shows the grown crystal and wafers. Microgravity experiments on the growth yielded crystals with reduced segregation of InBi [11.94]. This is one avenue that could be explored for higher incorporation of Bi in the crystal, thereby improving suitability for device applications.

11.5.5 Growth of Thick Layers of InSb, $\text{InAs}_x\text{Sb}_{1-x}$, and $\text{InBi}_x\text{Sb}_{1-x}$, by Liquid-Phase Epitaxy

LPE, although a widely used general laboratory preparation technique, has not found much favor with these materials, mainly due to the low temperatures of growth, limited by the melting point of InSb. However, recently there has been renewed activity on LPE growth of these materials. Here we present a comprehensive report on the growth of InSb-based epitaxial layers grown using LPE. These layers mimic the bulk-like properties and can also be used as virtual epi-ready wafers for further growth of multilayered structures.

InSb Epilayers

Various efforts have been made to adapt LPE for growth of InSb. Kumagawa et al. [11.111] reported dopant

Fig. 11.8a,b The two typical shapes of growth islands: (a) triangular (60° angle) and (b) truncated triangular

modulation in InSb layers grown by liquid-phase electroepitaxy (LPEE). *Melngailis* and *Calawa* [11.112] reported growth of planar InSb laser structures by LPE. They used a stearic acid encapsulant for growth to avoid oxide layer formation during growth. *Holmes* and *Kamath* [11.113] have used infinite solution epitaxy to grow binary InSb and discussed the growth of continuous layers with constant ternary composition. However, other than a few early papers on homoepitaxy [11.111, 113], there are no reports on successful growth InSb/GaAs by LPE. Recently, *Dixit* et al. [11.10] reported successful epitaxial growth of

this material on SI-GaAs substrate by LPE with extremely low ramp cooling rates. Growth was carried out on (001) semi-insulating GaAs substrate in a boat-slider-type LPE unit [11.114, 115]. The optimized III/V mass ratio used for the growth was ≈ 3.45 . A ramp cooling routine was adopted with the intention of providing a driving force $\beta \propto \Delta T/T_g$ [11.116] (where ΔT denotes the supercooling of the solution and T_g the initial growth temperature) at every point of growth and induce orderly epitaxial growth. The sliding was achieved by an improvised electromechanical system. Films were grown under varied conditions of supersaturation by changing the ramp rate R and the cooling temperature step ΔT . During the course of this study, it was noticed that higher cooling rates led to formation of interesting island morphology. The two typical shapes were (a) triangular (60° angle) and (b) truncated triangular islands (Fig. 11.8). The results from various growth experiments are presented in Table 11.1. It is seen that the growth rate r ($\mu\text{m/h}$) and the ramp rate R have a direct correspondence as expected. Furthermore, as can be seen from Table 11.1, oriented films were grown only at $R = 0.2$ K/h, with ΔT of 2 K. Although oriented films were obtained by this way, coverage was low and morphology was poor. By increasing the growth temperature while keeping other conditions the same the growth rate could be decreased (#48A to #33B in Table 11.1), which is in agreement with *Elwenspoek's* work [11.116]. By initiating the growth at 423 °C and decreasing the ramp rate to 0.2 K/h, oriented films of 3 μm thickness could be grown.

InAs_xSb_{1-x} Epilayers

Until the 1990s growth of InAs_xSb_{1-x} by LPE was achieved only for very high arsenic concentrations (for 3–5 μm gap) and on nearly lattice-matched InAs and

GaSb substrates [11.117, 118]. However, there does not seem to be any work on LPE growth of this system for low values of *x*. This is primarily due to problems associated with the low growth temperature and large lattice mismatch. Recently a few more results have been published on this growth by authors such as Dixit et al. [11.5], Peng et al. [11.34], and Gao et al. [11.37], employing LPE or melt epitaxy (ME). Dixit et al. [11.5] grew InAs_xSb_{1-x} layers in the same boat-slider-type LPE unit used to grow InSb. Prior to growth, indium-rich InAsSb solution was prepared with indium and previously grown InAs_xSb_{1-x} crystals [11.9]. The optimized In/(Sb + As) mass ratio used for the growth was ≈ 2.93. The solution temperature was increased to 5 °C above the growth temperature of 446 °C, and baking for 6 h was used to allow proper homogenization. Here also a ramp cooling routine was used. The results obtained under various growth conditions are summarized in Table 11.2. Large growth rates force nucleation with off-(100) orientation, while oriented growth takes place on (100) GaAs at lower growth rates. It is to be noted that, when growth temperature increases above 446 °C, the arsenic incorporation into InSb increases due to the diffusion of arsenic from the GaAs substrate itself [11.119, 120]. Hence growth temperature was restricted to 446 °C. This led to the limitation of As incorporation to only 6 at. % in InAs_xSb_{1-x} epitaxial layers. Also it was observed that the quality of the interface deteriorated with increasing arsenic composition. This is due to a miscibility gap in the phase diagram. Recently, relatively thick films (100–200 μm) were grown by Gao et al. [11.37] using ME at 600 °C. Very recently Peng et al. [11.34] also reported predominantly oriented growth of InAs_xSb_{1-x} films with up

to 30% As incorporation using conventional LPE. In this work, layers were grown at constant growth temperatures rather than employing a ramp cooling routine. Constant growth temperature helps the compositional uniformity of the InAs_xSb_{1-x} films in the growth direction, similar to the observation of Dixit et al. [11.5] (by very slow growth rate condition).

InBi_xSb_{1-x} Epilayers

Literature on LPE growth of InBi_xSb_{1-x} is very limited. There are only a few reports on homoepitaxy of InBi_xSb_{1-x}. Ufimsev et al. [11.121] reported the growth for *x* = 0.01–0.02. Gao and Yamaguchi [11.122] also reported homoepitaxy of InBi_xSb_{1-x} using LPE, wherein they found that surface morphology was strongly dependent on cooling rate. Also Bi metal particles appeared on the surface of the epilayer. The cutoff wavelength reported for this film was 14 μm. Many reports can however be found in the literature on the heteroepitaxy of InBi_xSb_{1-x} using a variety of other techniques. Dixit et al. [11.123] also reported growth of InBi_xSb_{1-x} on GaAs using the boat-slider-type LPE unit. The optimized In/(Sb + Bi) mass ratio used for the growth was ≈ 1.86. The solution temperature was increased to ≈ 50 °C above the growth temperature (351 °C), and baking for a period of 6 h in ultra-pure hydrogen ambient was used for homogenization. Table 11.3 gives the correlation between imposed supersaturation ΔT (K) and the thickness of the grown films.

Work on the growth of InBi_xAs_ySb_{1-x-y} by a variety of techniques has also been reported, including LPE [11.4, 8, 53, 124–126]. However, extensive work is needed for the development of the Sb-based stable detectors for the long-wavelength region.

11.6 Structural Properties of InSb, InAs_xSb_{1-x}, and InBi_xSb_{1-x}

Structural information is crucial for developing any technology. Particularly it is very important to understand the role of alloying and mismatch epitaxy in these systems. Structural information about these materials is obtained using various characterization techniques. The most commonly used techniques include high-resolution x-ray diffraction (HRXRD), chemical etching, x-ray topography, atomic force microscopy (AFM), scanning electron microscopy (SEM), and transmission electron microscopy (TEM).

11.6.1 InSb

Composition

Although InSb growth is very well studied, care must be taken to obtain crystals in stoichiometric form. Hence the starting material for all growth runs should be synthesized in one batch to avoid any batch-to-batch variation in composition, and care must be taken in transferring the material and to maintain accuracy to the level of $\mu\text{g/g}$ of charge. Also, due to the vapor pressure difference, composition differences of the starting material have to be taken into account. The typical results of energy-dispersive x-ray analysis (EDAX) for samples made from grown InSb crystals showed that the crystals were radially and axially homogeneous. The typical radial composition profile for 20 mm InSb wafer is given in Table 11.4.

Orientation Determination

The crystallographic orientation of the grown crystals can be determined from x-ray diffraction experiments. The Laue pattern shows fourfold symmetry for $\langle 001 \rangle$ and threefold symmetry for $\langle 111 \rangle$ InSb wafer. From powder x-ray diffraction scans of the wafer one can

determine the growth direction of the crystals. For example, a single peak corresponding to (111) and $(1\bar{1}\bar{1})$ planes is obtained for wafers made from crystals grown by horizontal and vertical Bridgman techniques.

Chemical Etching

InSb is the most perfect material among the III–V semiconductors available to date. For chemical etching, usually CP4 etchant has been found to be very effective (Fig. 11.9). Chemical etching producing pits has been used to quantify dislocations. In InSb, a one-to-one correspondence has been established between dislocations and etch pits. The pit count, EPD, gives an order of magnitude estimate of the dislocation content in the crystals. Typically $10\text{--}100\text{ cm}^{-2}$ etch pit density is specified in commercially available InSb. However, the best results are only 1 etch pit in 50 cm^2 . T-shaped and *star*-type arrays of etch pits are more prominent in InSb due to an inherent difference between the (111) and $(\bar{1}\bar{1}\bar{1})$

Fig. 11.9 Etch pit pattern on (111) InSb wafer

Table 11.4 Compositional profile of InSb wafer; *a*, *b*, *c*, *d* are marked in the schematic of the wafer shown at the top of the table

<div><div></div><div>Compositional profile</div></div>					
From <i>a</i> to <i>b</i>	Atomic percentage		From <i>c</i> to <i>d</i>	Atomic percentage	
	In	Sb		In	Sb
1. (1 mm)	50.10	49.85	1. (1 mm)	50.09	49.91
2. (6 mm)	50.07	49.93	2. (7 mm)	50.11	49.89
3. (12 mm)	50.19	49.81	3. (13 mm)	50.19	49.81
4. (19 mm)	50.10	49.9	4. (20 mm)	50.23	49.77

planes [11.96]. Also this polarity influences many other properties; for example, damage depth and chemical attack rates are different for 111B (Sb planes) and 111A (In planes).

Slip System

{111} are the slip planes for InSb. The slip direction is one of the $\langle 110 \rangle$ directions. If InSb crystals are compressed or bent by applying stress above a critical value, arrays of slip dislocations can be produced, which can be viewed as etch pit arrays defining the traces of the {111} planes.

Twinning

During growth, a 60° lattice rotation about any III–V bond in a $\langle 111 \rangle$ direction preserves the tetrahedron of opposite species but in a lattice mirrored across the (111) plane, since both the nearest and second nearest neighbors remain at their normal distance; the energy required for this twinned growth is exceptionally low. For this reason twinning across the set of {111} planes is the principal complication in growing single crystals of InSb. Various other types of twinning are also reported along {211} and {111} planes for III–V as well as IV semiconductors but not in InSb [11.96, 127]. *Terashima* [11.98] reported Y-shaped defects in (111) pulled InSb crystals and these defects are eliminated by growing the crystal using a seed inclined at $5\text{--}10^\circ$ from (111) towards $\langle 110 \rangle$.

High-Resolution X-Ray Diffraction Study

An ideal crystal on interaction with a x-ray beam diffracts a beam of extremely narrow width at the Bragg angle. However, in practice one sees a width of diffracted beam or rocking curve width of several hundreds of arc seconds in angular spread. This was first explained by *Darwin* [11.128], considering the crystal to be a macromosaic of crystals of slightly differing orientations. These macromosaics receive the x-ray at different incident angles and hence there is a finite spread in the resultant diffracted beam. Also, defects in the lattice such as vacancies, interstitial, dislocations, twins, and small-angle grain boundaries distort the lattice and contribute to broadening of the rocking curve. The relative widths of diffraction curves have been found useful for comparing the crystalline perfection of many semiconductors. Such studies have been made on InSb and are described by *Auleymer* [11.129]. High-resolution x-ray diffraction study is very effective for determining the crystalline quality [11.130] of InSb crystals. *Gartstein* and *Cowley* [11.131] and

Fig. 11.10 X-ray diffraction patterns (ϕ scan) of single crystal and epilayers in asymmetric (115) reflection over 360° azimuths

Gartstein et al. [11.132] discuss the x-ray diffraction study of perfect and In^+ -ion-implanted InSb single crystals. The rocking curves of these crystals are relatively large; however substantial reduction in radiation damage by permanent magnetic fields is noticed. Recently, *Dixit* [11.11, 69] carried out HRXRD studies on bulk InSb and Li:InSb using a Philips X'PERT high-resolution x-ray diffractometer. A ϕ scan of an asymmetric reflection was performed to determine the single-crystal nature of the bulk InSb crystal. As seen in Fig. 11.10 the ϕ scan over 360° azimuths gave four distinct peaks separated by 90° intervals with no scattering between them, confirming the single-crystalline nature of InSb. Subsequently several symmetric and asymmetric rocking curves were recorded. The rocking curve width (full-width at half-maximum, FWHM) was found to be $18''$ (Fig. 11.11), which is approaching the theoretical limit of the rocking curve width for 004 reflection of InSb. Employing MOCVD *Gaskill* et al. [11.29] have grown layers of InSb on InSb substrates with rocking curve width of $34''$, approaching the theoretical limit of $11''$ for InSb. Interesting studies on the structural dynamics of InSb using time-resolved x-ray diffraction were reported by *Chin* et al. [11.133]

Synchrotron Radiation Topographic Study

Surowiec and *Tanner* [11.134] reported transmission x-ray topography studies on the dislocation configurations around microindentations on {111} surfaces

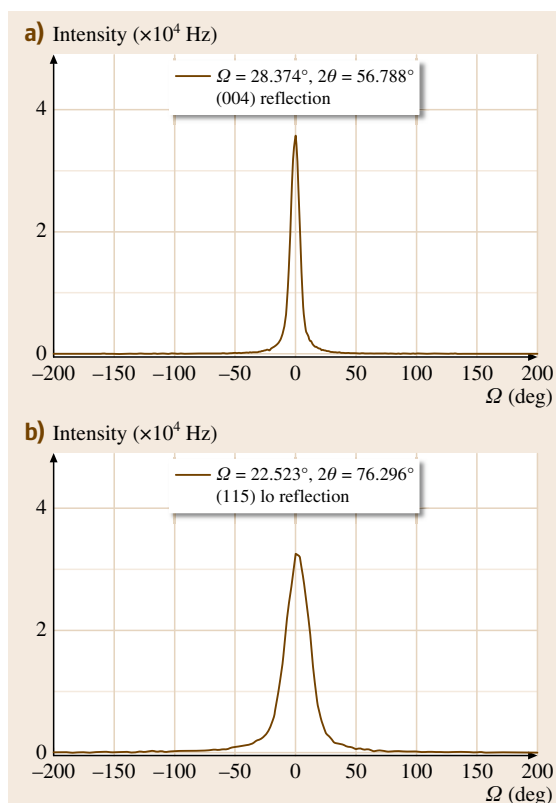

Fig. 11.11a,b Representative $\omega/2\theta$ scans of InSb for (a) (004) reflection and (b) (115) lo reflection

of InSb. Glide occurs on only B-type {111} planes, and the most extended dislocation loops occur around A-surface indents. Glide occurs on inclined {111} planes and the loops have extended screw segments parallel to the surface. The mobility of these dislocations is about two or three times less than the former type. Direct evidence for the formation of edge dislocation barriers from reactions between dislocations gliding in the (111) plane is reported. Dixit et al. [11.69] also carried out synchrotron x-ray topographic study on high-quality InSb crystals. Reflection topographs of polished surfaces were taken with the normal tilted 5° from 024 reflection. A diffraction wavelength of 1.30 \AA was used, and the sample-to-film distance was 20 cm. Results are shown in Fig. 11.12a,b. As can be seen from the figure, the topographic images are free from asterism. Surfaces show some polishing effects but they are free from any dislocation. Figure 11.12b shows some white circular features which are due to metal inclusions.

Fig. 11.12 Synchrotron reflection topographs of InSb wafers

11.6.2 $\text{InAs}_x\text{Sb}_{1-x}$

Dixit et al. [11.9, 69] estimated arsenic content in grown $\text{InAs}_x\text{Sb}_{1-x}$ crystal by measuring the melting point using differential scanning calorimetry and inferred that it must be more than 3 at.% (Fig. 11.13). The composition x in $\text{InAs}_x\text{Sb}_{1-x}$ crystals grown from starting proportions of 95 : 5 and 90 : 10 was 0.02 and 0.05, respectively, as determined from EDAX. Further confirmation of the composition was made using x-ray photoelectron spectroscopy (XPS). The binding energies were measured with respect to the 1s peak at 285 eV with a precision of $\pm 0.1 \text{ eV}$. XPS of core-level regions of In(3d), Sb(3d), and As(3d) are shown in Fig. 11.14. Spin-orbit doublet peaks of In($3d_{5/2,3/2}$), Sb($3d_{5/2,3/2}$), and As($3d_{5/2,3/2}$) show shifts compared with the respective metals [11.135]. The surface concentration ratio In(3d)/Sb(3d) has been estimated using the following

equation

$$\frac{C_{\text{In}}}{C_{\text{Sb}}} = \frac{I_{\text{In}} \sigma_{\text{Sb}} \lambda_{\text{Sb}} D_{\text{E}}(\text{Sb})}{I_{\text{Sb}} \sigma_{\text{In}} \lambda_{\text{In}} D_{\text{E}}(\text{In})}, \quad (11.3)$$

where C , I , σ , λ , and D_{E} are the concentration, intensity, photoionization cross section, mean escape depth [11.135–137], and geometric factor respectively. Integrated intensities of metal peaks have been

Fig. 11.14 X-ray photoelectron spectra of $\text{InAs}_{0.05}\text{Sb}_{0.95}$ for In, Sb, and As

Fig. 11.13 Differential scanning calorimetry curves of $\text{InAs}_x\text{Sb}_{1-x}$ for $x = 0$ and 0.05

taken into account for calculating the concentrations. Surface concentration ratios of $\text{In}(3d)/\text{Sb}(3d)$ and $\text{As}(3d)/\text{Sb}(3d)$ can also be calculated using similar equations. The composition has been estimated to be $\text{InAs}_{0.055}\text{Sb}_{0.945}$, which is close to the bulk composition obtained from EDAX. From EDAX and XPS results

Fig. 11.15 X-ray diffraction peaks of single-crystal wafers of InSb and $\text{InAs}_{0.05}\text{Sb}_{0.95}$ for (111) reflection

Fig. 11.16 (a) Bright-field image of $\text{InAs}_{0.05}\text{Sb}_{0.95}$, (b) selected-area diffraction pattern of (a), and (c) bright-field image showing dislocations along the $\langle 110 \rangle$ direction

it was concluded that the grown crystals were radially homogeneous but the As composition decreased from tip to the other end of the ingot. The lattice parameter

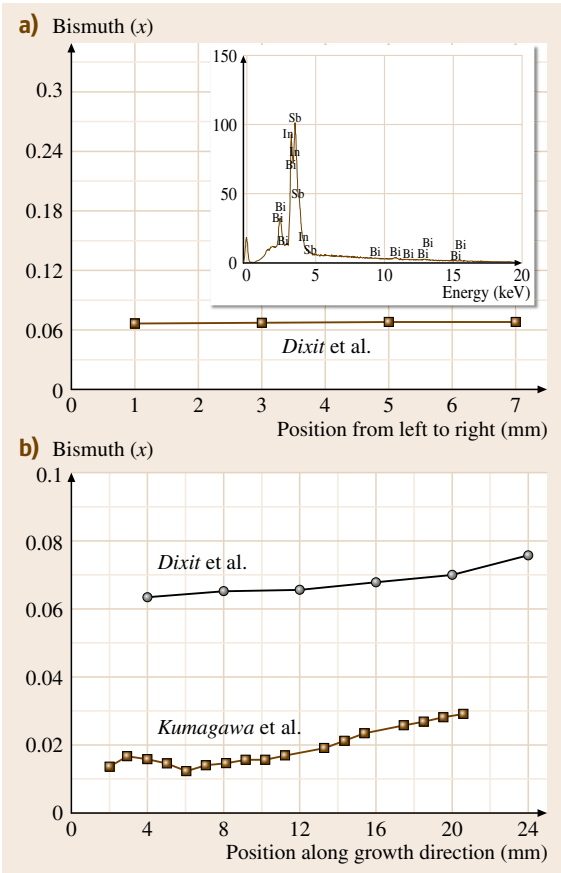

of $\text{InAs}_{0.05}\text{Sb}_{0.95}$ as calculated from XRD powder patterns is $6.460 \pm 0.006 \text{ \AA}$ and matches reasonably with that obtained from Vegard's law. $\text{InAs}_{0.05}\text{Sb}_{0.95}$ showed lattice contraction relative to that of InSb, as confirmed by XRD (Fig. 11.15). Dixit et al. [11.9] also obtained bright-field TEM images of $\text{InAs}_{0.05}\text{Sb}_{0.95}$ along with its selected-area electron diffraction pattern, confirming the absence of twinning (Fig. 11.16). However in the bright-field image, dislocations were observed primarily along $\langle 110 \rangle$ direction (Fig. 11.16). The estimated dislocation density was $\approx 10^8 \text{ cm}^{-2}$. This is comparable to those found for $\text{InAs}_x\text{Sb}_{1-x}$ alloy grown by other techniques [11.138].

11.6.3 $\text{InBi}_x\text{Sb}_{1-x}$

So far, the highest value of x in $\text{InBi}_x\text{Sb}_{1-x}$ bulk single crystals is 0.064 ± 0.01 , as determined from EDAX (inset in Fig. 11.17a). Dixit et al. [11.12] found that the Bi content in crystal grown by RBM increases from the tip to the upper end of the ingot, confirming that the equilibrium segregation coefficient of Bi in InSb is less than unity. Compared with Kumagawa et al. [11.110], they could achieve higher Bi incorporation into the crystals with better radial and axial homogeneity, as can be seen from Fig. 11.17. From powder x-ray diffraction patterns recorded for $\text{InBi}_x\text{Sb}_{1-x}$ the lattice parameter was calculated and found to be $6.489 \pm 0.006 \text{ \AA}$. The composition of Bi as evaluated by Vegard's law

$$a_{\text{InBi}_x\text{Sb}_{1-x}} = xa_{\text{InBi}} + (1-x)a_{\text{InSb}} \quad (11.4)$$

Fig. 11.17 (a) Radial and (b) axial compositional profiles of $\text{InBi}_x\text{Sb}_{1-x}$ crystal; inset in (a) shows a typical EDAX spectrum ◀

is 6.79 at. %, which is in reasonable agreement with the EDAX result, where

$$\begin{aligned} a_{\text{InBi}} &= 6.640 \text{ \AA} \quad [11.39] \quad \text{and} \\ a_{\text{InSb}} &= 6.478 \text{ \AA}, \\ a_{\text{InBi}_x\text{Sb}_{1-x}} &= 6.490 \pm 0.006 \text{ \AA}. \end{aligned}$$

11.6.4 InSb, InAs_xSb_{1-x}, and InBi_xSb_{1-x} Grown on GaAs

Dixit et al. [11.10, 115] carried out extensive HRXRD studies on these heterostructures grown using LPE. A ϕ scan of an asymmetric reflection recorded on InSb/GaAs gave four distinct layer peaks separated by 90° intervals with negligible scattering between them (Fig. 11.10). Layers show structural coherence with substrates as confirmed from various reflections (Fig. 11.18). The tilt angle T_{1s} of the epilayer to the substrate was estimated by using the relation

$$T_{1s} = \frac{1}{2} [(\Delta\omega_1 - \Delta\omega_3)^2 + (\Delta\omega_2 - \Delta\omega_4)^2]^{1/2}, \quad (11.5)$$

where the $\Delta\omega_i$ are the peak separations at 90° intervals. The tilt was found to be quite small and was about 0.01°. Strain parameters were evaluated by a least-squares routine for the following relationship [11.139]

$$\Delta\omega = k_1\epsilon_{\perp} + k_2\epsilon_{\parallel}, \quad (11.6)$$

where $k_1 = \cos^2\phi \tan\theta_B + 1/2 \sin 2\phi$ and $k_2 = \sin^2\phi \times \tan\theta_B - 1/2 \sin 2\phi$, in which θ_B is the substrate Bragg angle and ϕ is the angle between the reflecting plane (hkl) and the sample surface (001) with ϕ being positive (negative) for low (high) glancing incidence. The perpendicular and in-plane x-ray strain parameters, ϵ_{\perp} and ϵ_{\parallel} , in the above relationship are defined [11.140]

Fig. 11.18 Representative ω scans of InSb/GaAs for (004) reflection at four azimuths

with respect to the substrate lattice parameter as

$$\epsilon_{\parallel} = \frac{a_{\parallel} - a_s}{a_s}, \quad \epsilon_{\perp} = \frac{a_{\perp} - a_s}{a_s}, \quad (11.7)$$

where a_{\parallel} and a_{\perp} are the in-plane and out-of-plane lattice constants, respectively. The results of the least-square analysis are $\epsilon_{\parallel} = (99 \pm 10) \times 10^{-3}$ and $\epsilon_{\perp} = (108 \pm 3) \times 10^{-3}$, indicating considerable in-plane strain relaxation expected for the large mismatch. From these results they determined $a_{\parallel} = 6.213 \text{ \AA}$ and $a_{\perp} = 6.264 \text{ \AA}$, both approaching the standard lattice constant of InSb. The in-plane and out-of-plane residual strains as evaluated from a_{\parallel} and a_{\perp} are 0.0409 and 0.033, respectively, which are quite small. All the films shows almost complete relaxation, hence extensive dislocation network is to be expected, which was estimated using the FWHM of symmetric (004) reflec-

Fig. 11.19 (a) Scanning electron micrograph of InSb/GaAs interface, (b) bright-field image of the InSb/GaAs cross-section, and (c) selected-area diffraction pattern of ((b))

tion. With the magnitude of the Burger's vector taken as $1/(2\sqrt{2})a$ (which is the case for 60° misfit dislocation), where a is $(a_{\text{InSb}} + a_{\text{GaAs}})/2$ [11.141], the estimated average dislocation density is in the range $1.3 \times 10^9 - 4.7 \times 10^{10} \text{ cm}^{-2}$, which compares favorably with the values reported for epitaxial layers grown by MBE and MOCVD [11.28, 29].

The cross section of the film (cleaved sample) observed under a scanning electron microscope (SEM), shown in Fig. 11.19a, clearly reflects reasonable sharpness of the interface between the InSb layer and GaAs substrate. The bright-field cross-sectional TEM image,

taken with a JEM-200CX transmission electron microscope, indicates a sharp interface with very small coalescing islands (marked "C" in Fig. 11.19b). The selected-area electron diffraction pattern of an InSb–GaAs interface is shown in Fig. 11.19c. The diffraction spots occur in pairs, corresponding to InSb and GaAs, respectively, indicating that the layer and the substrate are epitaxially oriented. Very similar results were obtained for $\text{InAs}_x\text{Sb}_{1-x}/\text{GaAs}$ and $\text{InBi}_x\text{Sb}_{1-x}/\text{GaAs}$ heterostructures, confirming that heteroepitaxy is more dominant than alloying effects for these structures for small composition.

11.7 Physical Properties of InSb, $\text{InAs}_x\text{Sb}_{1-x}$, and $\text{InBi}_x\text{Sb}_{1-x}$

It is known that III–V compounds have band structures nearly similar to those of group IV semiconductors, although there are some differences which arise from the lack of inversion symmetry in their crystal structures. The effective mass of electrons in the conduction band varies from compound to compound and is the smallest for InSb-based materials amongst all III–V compounds. The effective masses of heavy holes, however, do not seem to vary much in these compounds. The strong interaction between the valence and conduction bands results in nonparabolicity at the bottom of the conduction band in these materials. Hence their electrical and optical properties are different from various other compound semiconductors.

11.7.1 Band Structure of InSb, $\text{InAs}_x\text{Sb}_{1-x}$, and $\text{InBi}_x\text{Sb}_{1-x}$

The band structure of InSb was calculated using the $\mathbf{k} \cdot \mathbf{p}$ perturbation approach [11.142]. Various authors have postulated the band structure of InSb and experiments have verified the same. Experiments show that the minimum of the conduction band in indium antimonide lies at the center of the zone and that the band is spherically symmetrical. The most direct evidence for the spherical symmetry of the band has come from microwave cyclotron resonance experiments [11.143]. For a band with spherical symmetry, the longitudinal magnetoresistance should be zero, and it has been found experimentally in n-type InSb that it is indeed an order of magnitude smaller than the transverse magnetoresistance [11.144]. The effective mass of electrons at the bottom of the conduction band in InSb is only $0.013(\pm 0.001)m_0$ [11.143]. This very small effective

mass means that the band has very high curvature and very low density of states at its minimum. As a result a small number of electrons fill the band to high energy levels [11.143]. Hence material becomes degenerate at relatively low electron densities and the height of the Fermi level above the bottom of the conduction band increases rapidly with electron concentration. At a temperature T the conduction band is filled up to a level which is about $4k_B T$ below the Fermi level, so that in an impure sample the transitions are to a level well above the bottom of the conduction band. In this case the optical energy gap increases with electron concentration as

$$\Delta E = \Delta E_0 + \left(1 + \frac{m_e}{m_h}\right)(\zeta - 4k_B T), \quad (11.8)$$

where ζ is the height of the Fermi level above the bottom of the band and ΔE_0 is the difference between the conduction-band minimum and the valence-band maximum. A striking property of electrons in the conduction band of indium antimonide is their very large magnetic moment, which is a consequence of interaction between the conduction and valence bands [11.145]. The g factor can be evaluated from

$$g = 2 \left[1 - \left(\frac{m_0}{m_e} - 1 \right) \left(\frac{\Delta}{3E_g + 2\Delta} \right) \right], \quad (11.9)$$

where Δ is the spin–orbit interaction and E_g is the energy gap. The measured g values decrease from -50.7 for $2 \times 10^{14} \text{ cm}^{-3}$ to -48.8 for $3 \times 10^{15} \text{ cm}^{-3}$ electron concentration. The theoretical work on InSb suggests the existence of three valence bands: a *heavy-hole* band V_1 , a *light-hole* band V_2 , degenerate with V_1 at $\mathbf{k} = 0$, and a band V_3 due to spin–orbit coupling (Fig. 11.20a).

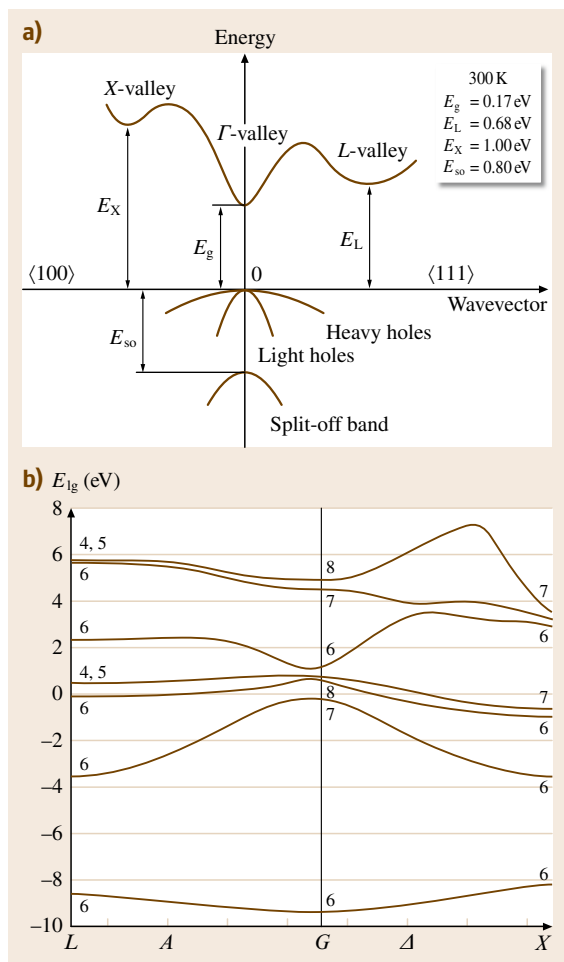

Fig. 11.20a,b Band structures of (a) InSb and (b) InBiSb (after [11.149])

The effective mass of the heavy hole lies in the range $0.55m_0 < m_h < 0.72m_0$ and that of the light hole is $0.015m_0$. The spin-orbit splitting of the valence band is estimated to be about 0.8 eV. The maximum of the valence band is not exactly at $k = 0$ but is displaced in the $\langle 111 \rangle$ direction, although it is difficult to resolve this displaced maxima experimentally because of the small energy (10^{-4} eV). Since the momentum offset is so small in InSb it behaves as a direct-gap semiconductor. Magnetoresistance measurements have been used to measure the shape of the valence band [11.146]. The band structure for $\text{InAs}_x\text{Sb}_{1-x}$ has also been studied within the framework of $k \cdot p$ theory and using this the variations of effective masses and g factor with composition were reported. By modifying the $k \cdot p$

theory and taking into account a multiband approximation as well as modified matrix elements the precise values of m and the g factor were obtained by *Hermann and Weisbuch* [11.147]. Furthermore, spin-orbit splitting of $\text{InAs}_x\text{Sb}_{1-x}$ has been studied by several authors [11.147, 148]. They reported values quite different from those calculated by a virtual-crystal approximation in which fluctuations in the crystal potential had been neglected. However, for very small values of x ($0 < x < 0.07$) both give similar values.

The band structure of $\text{InBi}_x\text{Sb}_{1-x}$ has been studied extensively by *Vyklyuk et al.* [11.149]. They calculated the electronic band structure of $\text{InBi}_x\text{Sb}_{1-x}$ for $x = 0.05$ using a local empirical pseudopotential with spin-orbit interaction in the virtual-crystal approximation (Fig. 11.20b). Utilizing this band structure they calculated the absorption coefficient, which closely matches experimental values.

11.7.2 Transport Properties of InSb, $\text{InAs}_x\text{Sb}_{1-x}$, and $\text{InBi}_x\text{Sb}_{1-x}$

InSb

Intrinsic carrier concentration is of fundamental importance for semiconductors and their application in devices. Knowledge of the intrinsic carrier concentration should help in understanding the performance of detectors. At moderate carrier densities, the degeneracy in InSb varies considerably in the temperature range of measurements [11.150]. This has a significant effect in determining the temperature dependence of transport properties. At room temperature, the intrinsic carrier density in InSb is $\approx 2.02 \times 10^{16} \text{ cm}^{-3}$, which is often larger than the background doping. Therefore, even in n-type doped samples, transport experiments must be considered in the light of ambipolar conduction [11.151]. Figure 11.21 shows a plot of the intrinsic carrier concentration n_i as a function of temperature. Since the heavy holes are ≈ 50 times heavier than the light holes (which have almost the same effective mass as the conduction electrons) they have a correspondingly larger relative population density at a given temperature. The purest InSb crystals reported contained less than 10^{13} donors/ cm^3 [11.152], but most of the information available on electrical properties refers to crystals with impurity concentration greater than 10^{14} cm^{-3} . The Hall coefficient in n-type samples varies little with temperature below 100 K. Above 150 K the purest sample is intrinsic. In n-type InSb the donor levels are merged with the conduction band, and at temperatures below the intrinsic range,

Fig. 11.21 Calculated intrinsic carrier concentration in InSb and $\text{InAs}_x\text{Sb}_{1-x}$ as a function temperature

the concentration of conduction electrons does not decrease with temperature. Thus at this point material behaves like a metal, with few charge carriers of high mobility.

The temperature dependence of conductivity and Hall data were reported by many groups [11.153–155]. Vinogradova and coworkers [11.156, 157] have reported room-temperature mobilities higher than $100\,000\text{ cm}^2/(\text{V s})$ in specimens with donor concentration of 10^{13} cm^{-3} . A more likely value for samples with donor concentration lower than $5 \times 10^{14}\text{ cm}^{-3}$ is 78 000 or 65 000, where the Hall factor (r_H) is taken as 1 or $\frac{3}{8}\pi$, respectively. The highest value reported for electron mobility at 77 K is $1.1 \times 10^6\text{ cm}^2/(\text{V s})$ for samples with donor concentration of $8 \times 10^{12}\text{ cm}^{-3}$ [11.152]. The highest reliable hole mobility value at room temperature is $750\text{ cm}^2/(\text{V s})$ and that at 77 K is $10\,000\text{ cm}^2/(\text{V s})$. The mobility ratio (b) is also temperature dependent and for pure specimens is $\approx 6.3 T^{1/2}$ above 250 K. At room temperature b is just 100. In impure specimens b is rather lower because the mobility of electrons is affected more than that of holes by impurity scattering. Madelung and Weiss [11.158] using resistivity data measured the thermal energy gap in InSb at 0 K to be 0.265 eV. Hrostowski et al. [11.153] also estimated it to be between 0.26 and 0.29 eV. Recently Bansal and Venkataraman [11.151] probed the effect of Landau level formation on the population of intrinsic electrons in InSb near room temperature in magnetic fields up to 16 T. Although the measured magnetic field

dependence of the Hall coefficient is qualitatively similar to the published results, it is shown that the data may also be explained by simply including ambipolar conduction. Thus, the inference on band depopulation drawn from previous measurements on InSb is inconclusive unless both the Hall and magnetoresistive components of the resistivity tensor are simultaneously measured and modeled. When the model includes both depopulation and ambipolar conduction, reasonable agreement with theory can be achieved. Drachenko et al. [11.159] experimentally reevaluated the effective mass of electron in InSb for two different g -factor values. It was found that the effective mass m_e was equal to $0.0127m_0$ at 80 K for $g = 54$. On the other hand, taking the experimental value of g -factor reported by Miura et al. [11.160] as 70, m_e was evaluated as

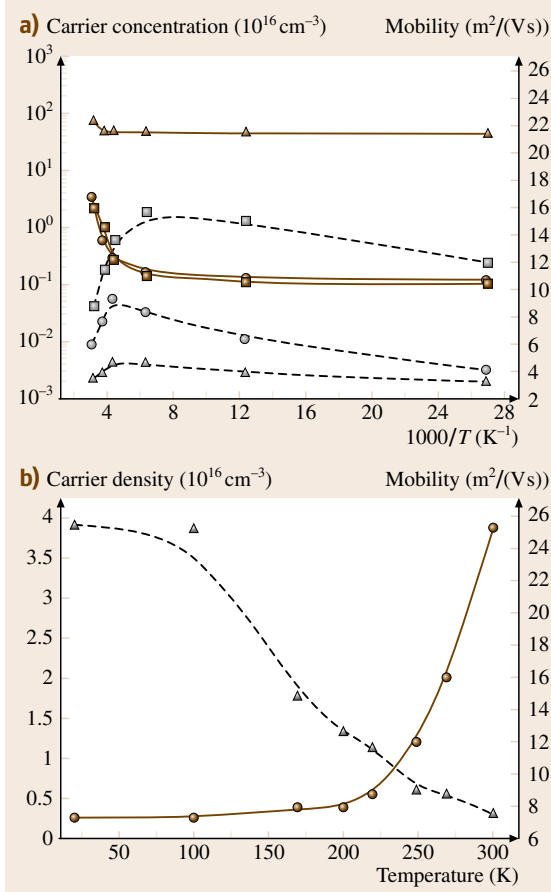

Fig. 11.22 (a) Hall data for InSb wafers grown from starting materials of different purity and (b) temperature-dependent Hall data of high-quality InSb wafer

0.0133 m_0 , which is very close to the recommended value (0.0135 m_0) for InSb at helium temperatures. A very comprehensive account of band structure effects and transport calculations in narrow-gap semiconductors can be found in the book by Nag [11.161] and review articles by Zawadzki [11.162]. Recently Bansal and Venkataraman [11.151] and Dixit et al. [11.10, 115] have reported transport properties of these materials in both the bulk and epitaxy forms. Strong effects of impurities in the starting materials on carrier density variation as a function of temperature have been noticed (Fig. 11.22a) [11.115]. The bulk InSb sample may be taken as a reference against which the effects of epitaxy and alloying can be compared. The temperature dependence of the measured carrier concentration and mobility for a bulk InSb sample is shown in Fig. 11.22b. The background doping of bulk InSb is a reasonable indicator of its properties. The low-temperature mobility and carrier concentration of bulk sample were at least an order of magnitude better than those of InSb epitaxial films grown from starting materials of the same purity (5 N).

InAs_xSb_{1-x}

Apart from disorder contributions, transport in InSb–InAs alloys may also be treated in a similar way to that of InSb. Only the band parameters, viz. the energy gap, the spin–orbit splitting, the effective masses, and phonon energies, need to be suitably determined at a given alloy concentration. For this the simplest method has been suggested by van Vechten [11.148] in a disordered virtual-crystal model for his quantum dielectric theory [11.163]. The first calculation of the intrinsic carrier concentration in InAs_xSb_{1-x} was carried out by Rogalski and Jozwikowski [11.18], who used a three-band approximation of $\mathbf{k} \cdot \mathbf{p}$ theory. The intrinsic carrier concentration and the reduced Fermi energy were calculated for InAs_xSb_{1-x} with $0 \leq x \leq 1$ and $50 \text{ K} \leq T \leq 300 \text{ K}$. By fitting the calculated non-parabolic n_i values to the expression for parabolic bands, the following equation for the intrinsic carrier concentration has been obtained

$$n_i = (1.35 + 8.50x + 4.22 \times 10^{-3}T - 1.53 \times 10^{-3}xT - 6.73x^2)T^{3/2}E_g^{3/4} \times \exp\left(\frac{-E_g}{2k_B T}\right) 10^{14}. \quad (11.10)$$

The calculated intrinsic carrier concentration in InAs_xSb_{1-x} (for lower values of As) as a function of temperatures has already been shown in Fig. 11.21.

As can be seen from Fig. 11.21, with increasing arsenic content the intrinsic carrier density increases. The conduction-band effective mass m_e was determined by Berolo et al. [11.164] for the whole range of compositions. The resultant conduction band effective mass m_e was given as

$$\frac{1}{m_e(x)} = \frac{1}{m_{ce}} + \frac{\delta E}{3} \left[\frac{1}{m_{hh}E_{gv}} + \frac{1}{m_{lh}E_{gv}} + \frac{1}{m_s(E_{gv} + \Delta_v)} - \frac{1}{m_{ce}} \left(\frac{2}{E_{gv}} + \frac{1}{E_{gv} + \Delta_v} \right) \right]. \quad (11.11)$$

In order to determine $m_e(x)$, all the parameters of above equation should be known. Here the difference $\delta E = E_{gv} - E_g$ is determined by the effects of the aperiodic potential due to disorder. E_{gv} and Δ_v are obtained

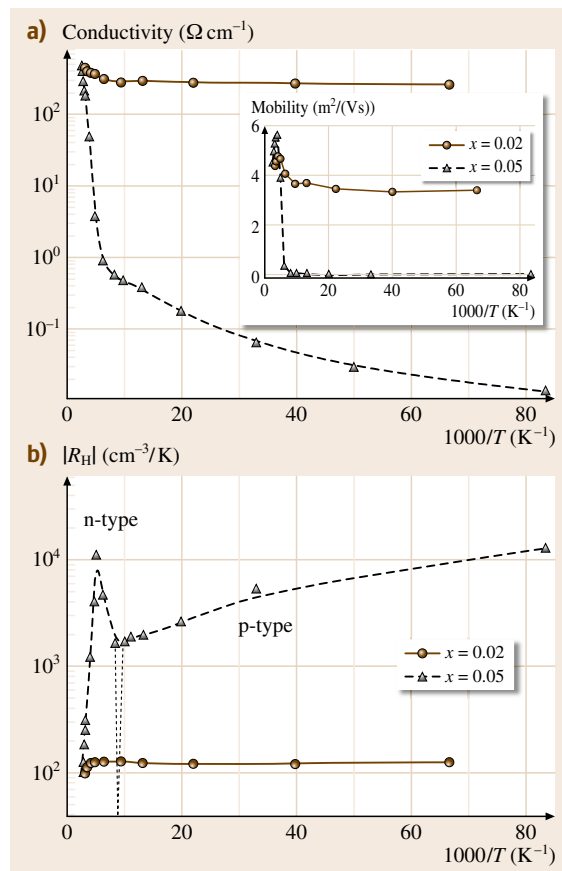

Fig. 11.23a,b Temperature dependence of (a) conductivity and mobility (inset) of InAs_xSb_{1-x} and (b) Hall coefficient

using the virtual-crystal approximation (VCA), which can be approximated by the expressions $E_{gv} = 0.351 - 0.0176x$ and $\Delta_v = 0.39 - 0.42x$ at 300 K. m_{lh} and m_{hh} are the light- and heavy-hole effective masses and m_{ce} is the effective mass for the conduction band in the absence of conduction–valence band mixing.

Resistivity and low-field (< 0.2 T) Hall coefficient for $\text{InAs}_x\text{Sb}_{1-x}$ samples with $x = 0.02$ and 0.05 were reported between 12 and 300 K [11.9]. The room-temperature (RT) mobility in the samples for $x = 0.02$ was $4.5 \times 10^4 \text{ cm}^2/(\text{V s})$ and that for $x = 0.05$ was $5.6 \times 10^4 \text{ cm}^2/(\text{V s})$. All samples with $x = 0.02$ were n-type and showed intrinsic behavior above ≈ 250 K. The representative results for $x = 0.02$ samples shown in Fig. 11.23a and b give a RT carrier concentration of $6.4 \times 10^{16} \text{ cm}^{-3}$ and a background doping of $5 \times 10^{16} \text{ cm}^{-3}$. On the other hand $\text{InAs}_{0.05}\text{Sb}_{0.95}$ shows a type conversion from n to p at 110 K. Below 77 K, the Hall coefficient and resistivity did not saturate and the conductivity below 30 K was strongly activated, indicating the presence of trap states. Further evidence of their presence is given by the pronounced tail in the absorption edge for this sample (as discussed in the next section). The hole mobility continuously dropped with decreasing temperature to $175 \text{ cm}^2/(\text{V s})$ at 15 K.

$\text{InBi}_x\text{Sb}_{1-x}$

Akchurin et al. [11.67] carried out experimental investigation on the behavior of Bi in $\text{InBi}_x\text{Sb}_{1-x}$ solid

solutions. It was found that bismuth doping in InSb strongly increases the electron density, which is due to the formation of Bi donor level [11.67]. An x-ray structure investigation indicated that this level is due to a complex state of Bi in the InSb lattice, representing a simultaneous combination of the substitutional and interstitial components. In the entire range of composition $\text{InBi}_x\text{Sb}_{1-x}$ shows n-type behavior. The electron mobility of $\text{InBi}_x\text{Sb}_{1-x}$ films decreases as the Bi concentration increases. This decrease of mobility is attributed to random alloy scattering [11.67]. The temperature dependence of resistivity also reveals the donor nature of Bi in $\text{InBi}_x\text{Sb}_{1-x}$ [11.67]. Dixit et al. [11.12] also showed the donor nature of Bi in $\text{InBi}_x\text{Sb}_{1-x}$ system.

InSb , $\text{InAs}_x\text{Sb}_{1-x}$, and $\text{InBi}_x\text{Sb}_{1-x}$ Grown on GaAs

For these materials, the unintentional background doping levels for the epitaxial layers were all similar, at around $\approx 10^{16} \text{ cm}^{-3}$, almost an order of magnitude higher than that in pure bulk InSb prepared under similar conditions. The mechanism for this unintentional n-type doping is not clear, although material contamination during growth (or use of the starting material of lower purity [11.115]) was seen to increase the background doping levels and reduce the mobility (Fig. 11.24). The room-temperature mobility is $30\,000$ – $50\,000 \text{ cm}^2/(\text{V s})$ for InSb, $\text{InAs}_x\text{Sb}_{1-x}$, and $\text{InBi}_x\text{Sb}_{1-x}$ epilayers when grown from starting materials of the same purity (5 N). At around 275 K, the number of thermally generated electron–hole pairs become comparable to this background doping level and therefore the carrier concentration shows an activated behavior above this temperature. The activated region, when fitted to a relation $n_i = AT^{3/2} \exp(-E_g/2k_B T)$, yielded zero-temperature energy gap values of 0.23, 0.20, and 0.19 eV for InSb, $\text{InAs}_{0.06}\text{Sb}_{0.94}$, and $\text{InBi}_{0.04}\text{Sb}_{0.96}$, respectively, in reasonable agreement with more precise estimation from optical measurements (described in the next section). A comparison with published results indicates that both the carrier density and the mobility match with the results published on InSb, $\text{InAs}_x\text{Sb}_{1-x}$, and $\text{InBi}_x\text{Sb}_{1-x}$ epitaxial layers on GaAs, grown by MBE or MOCVD. Since between 10 and 250 K, an anomaly was observed in the carrier concentration for all the epitaxial layers, the measured Hall coefficient (R_H) showed a maximum at some intermediate temperature. In the past this has been attributed to multicarrier conduction, with contributions from interfacial, bulk, and possibly a sur-

Fig. 11.24 Temperature dependence of carrier concentration and mobility of InSb/GaAs

face layer, each with a different mobility, separately contributing to the total conductivity. However, LPE-grown epilayers are relatively thick and the observed properties did not correlate with film thickness. An

Fig. 11.25 Calculated temperature dependence of mobility due to various scattering mechanisms for $\text{InAs}_{0.06}\text{Sb}_{0.94}/\text{GaAs}$. alternative explanation in terms of variation of Hall factor (r_H) with the sample temperature and hence its degeneracy is more appropriate in this case. The Hall factor is exactly unity for a strongly degenerate sample but can take a larger value in nondegenerate samples, especially when long-range scattering potentials are active in limiting the sample mobility (e.g., $r_H = 1.93$ for ionized impurity scattering). The Hall factor for a partially degenerate gas, as in this case, can increase the measured Hall coefficient by $\approx 10\%$, which could explain the anomaly seen at most temperatures. The calculated temperature dependence of mobility due to various scattering mechanisms is shown in Fig. 11.25.

Magnetoresistance measurements were performed on $\text{InAs}_x\text{Sb}_{1-x}/\text{GaAs}$ by Bansal et al. [11.6]. The magnetoresistance signal starts as quadratic initially and becomes linear at higher magnetic fields (B), which is the expected behavior in the extreme quantum regime (Fig. 11.26). There was no magnetic-field-induced freeze-out observed at 4.2 K since, at background carrier densities of $\approx 10^{16} \text{ cm}^{-3}$, the impurity-band wavefunctions, even at 6 T magnetic field, have a spatial extent larger than the interimpurity separation because of the very small effective mass. There was no appreciable change in resistance or magnetoresistance between 4.2 and 30 K, again indicating that parallel conduction effects are not important since these are known to give an appreciable temperature dependence. Unlike in metals, the oscillations are not periodic in $1/B$ because of a considerable magnetic field dependence of the Fermi energy and unequal Landau level spacing due to nonparabolic energy dispersion. The amplitude of oscillations is extremely sensitive to sample homogeneity and therefore, although the $\mu B > 1$ condition was easily met, the oscillation amplitudes were small. This was the first time a Shubnikov signal in InAsSb has been observed. These results were further investigated in detail by Drachenko et al. [11.159], who reported the first experimental data for the calculation of the effective mass for $\text{InAs}_x\text{Sb}_{1-x}$. Using the expression for $E_g(T, x)$ in $\text{InAs}_x\text{Sb}_{1-x}$ alloys, they obtained m_e of $0.0122m_0$ and $0.0117m_0$ for $\text{InAs}_{0.04}\text{Sb}_{0.96}$, and $\text{InAs}_{0.06}\text{Sb}_{0.94}$ respectively.

$\text{InBi}_x\text{Sb}_{1-x}$ and $\text{InBi}_x\text{As}_y\text{Sb}_{1-x-y}$ also show n-type behavior over the entire temperature range. The maximum electron mobility was $3.54 \times 10^4 \text{ cm}^2/(\text{V s})$ and carrier concentration was $9.2 \times 10^{16} \text{ cm}^{-3}$ at 300 K for $\text{InBi}_x\text{Sb}_{1-x}$. Similarly $\text{InBi}_x\text{As}_y\text{Sb}_{1-x-y}$ has maximum electron mobility of $3.1 \times 10^4 \text{ cm}^2/(\text{V s})$ and carrier concentration of $8.07 \times 10^{16} \text{ cm}^{-3}$ at 300 K [11.8, 123].

11.7.3 Optical Properties of InSb, InAs_xSb_{1-x}, and InBi_xSb_{1-x}

The interest in antimonides is (to a large extent) because their energy gap is in the infrared. Optical properties of InSb have, of course, been long studied and are well understood [11.165, 166]. This section extends the studies to optical properties to determine the effect of alloying and heteroepitaxy on them.

InSb

In InSb, as the photon energy decreases past the value corresponding to the energy gap (0.17 eV), transmission shows a sudden increase until saturation, after which it remains constant or oscillatory (depending on the scattering process). From the position and shape of this *absorption edge* we obtain information on the nature of transition from valence band to conduction band. With further lowering of the photon energy (0.14 eV) the optical properties are affected by interaction between the photons and free carriers, and resulting transition takes place within the valence or the conduction bands. At still lower energy (0.09 eV) there can be interaction between photons and the lattice. The optical properties in this region are influenced both by the lattice and the free carriers and are being studied using Raman spectroscopy. The absorption edge of InSb is extremely steep and the absorption coefficients change by two orders of magnitude within a range of 0.01–0.04 eV. The position of the absorption edge will be dependent on pressure since compression of the lattice also changes the energy gap. The dimensions of the lattice also change when temperature is altered, but here there is an additional effect on the optical properties because the change in lattice vibration affects the width of the energy levels.

The wavelength dependence of free carrier absorption is therefore dependent on the scattering mechanism. At temperatures at which $k_B T \gg h\nu$, the square-law dependence is applicable for both acoustic and nonpolar optical scattering. When photon energy is greater than $k_B T$, the absorption is proportional to $\lambda^{3/2}$ for acoustic scattering but for optical scattering the dependence is more complicated. For impurity scattering, the absorption coefficient (α) is proportional to λ^3 . Kurnick and Powell [11.167] found that in InSb the free electron absorption had a λ^2 dependence, but the free-hole absorption was independent of wavelength. At 9 μm , the free-electron optical cross section ($= \alpha/n$) is $2.3 \times 10^{-17} \text{ cm}^2$ but the hole cross section is 40 times larger. The electron cross section is in good agreement with the theoretical value [11.167]. Measurements by Spitzer and Fan [11.168] on n-type InSb were extended to 35 μm and their results show that the square-law dependence is not obeyed at wavelengths longer than 12 μm . However, Moss [11.169] pointed out that the refractive index of InSb is not constant in this wavelength region. This theory gives the wavelength dependence of the product $\eta\alpha$ (where η is refractive index), and if the results of Spitzer and Fan are used in conjunction with

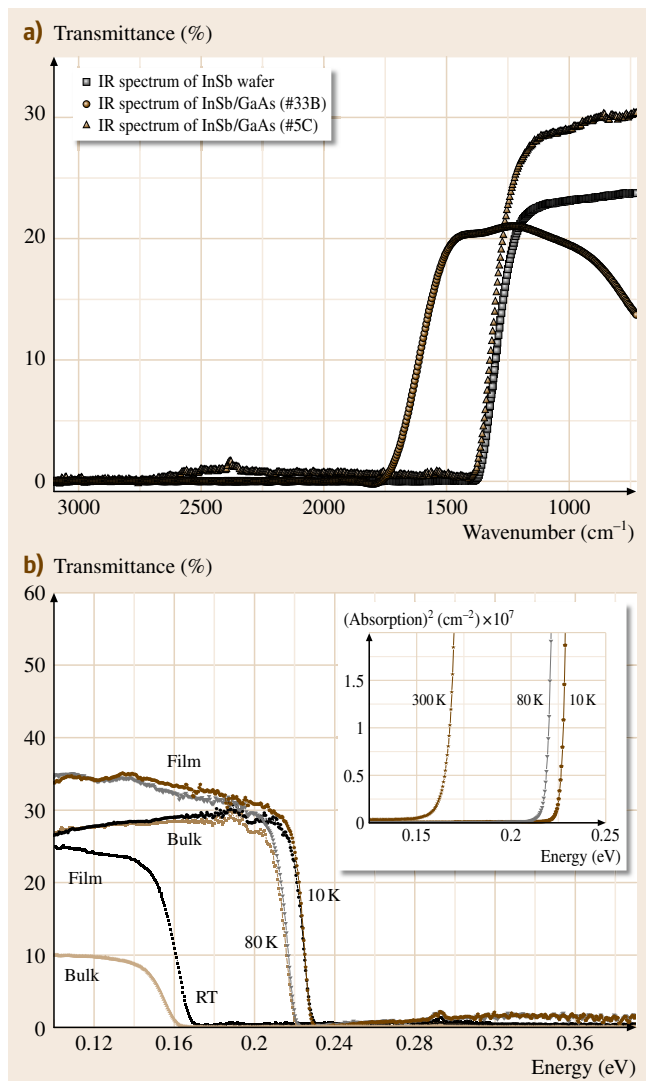

Fig. 11.27a,b Infrared spectra of InSb wafer and InSb/GaAs at (a) room temperature (b) different temperatures. The inset shows absorption squared versus energy plots at different temperatures

refractive index values, it is found that the product $\eta\alpha$ is proportional to λ^2 .

Recently Dixit et al. [11.115] observed that the absorption edge is shifted from the expected value towards higher energy to a different extent depending on the purity of the starting materials (Fig. 11.27a) similar to other report in literature [11.170]. Hence it is clear that the energy gap of InSb is very sensitive to impurities. The temperature dependence of the absorption edge is not significant for heavily doped materials because the Fermi level lies inside the conduction band. On the other hand the absorption edge for moderately doped or undoped InSb is very sensitive to temperature, as shown in Fig. 11.27b. The absorption coefficient was calculated from the transmission T , using the well-known expression that accounts for multiple reflections within the sample, viz. $T = ((1 - R)^2 e^{-\alpha d}) / ((1 - R)^2 e^{-2\alpha d})$. Here d is the thickness of the sample and $R = 0.4$ is the reflection coefficient, assumed to be constant in the spectral range of measurement. This equation is easily inverted by substituting $z = e^{-\alpha d}$ and then solving the quadratic equation in z . The energy gap, E_g , was obtained by fitting $\alpha = A(h\nu - E_g)^{1/2}$, to the experimental data around the absorption edge. Here α is the absorption coefficient in cm^{-1} , ν is the incident photon frequency, and A is a constant depending on the electron and hole effective masses and the optical transition matrix elements. The onset of absorption fits very well to the above relation, indicating a direct energy gap (inset of Fig. 11.27b). The energy gap was measured to be 0.172, 0.225, and 0.235 eV for RT, 80, and 10 K, respectively. The analysis of the temperature dependence of E_g is usually done by a three-parameter fit to Varshni's empirical relation [11.171], $E_g(T) = E_{gv}(0) - (\alpha T^2)/(\beta + T)$, where α and β are constants and $E_{gv}(0)$ is the energy gap at zero temperature. The energy gap of a semiconductor varies with temperature due to three distinct effects attributable to phonons [11.172]. These, all of similar importance, are the anharmonic (thermal expansion) and harmonic (Debye–Waller factor) phonon effects, and the temperature-dependent renormalization of the gap due to the electron–phonon self-energy correction (Fan's term). The value of the energy gap at different temperatures and the least-square fits to the above equation show good agreement. The fits yield $E_{gv}(0)$, α , and β as 0.235 ± 0.003 eV, $3.1 \pm 1.1 \times 10^{-4}$ eV/K, and 452 ± 190 K, respectively. These values and the temperature dependence of the energy gap are very similar to previous results [11.170], although these measurements were on wafers made from large-size crystals.

InAs_xSb_{1-x}

Woolley and Warner [11.13] carried out optical studies on InAs_xSb_{1-x} samples made by directional freeze and zone recrystallization methods. Although the energy values are determined on crudely prepared single crystal and polycrystals, the variation of energy gap with composition and temperature is reliable. The room-temperature values of E_g have been determined over the whole composition range. It is found that E_g falls as one compound is added to the other, the measured value of E_g reaching a minimum of 0.10 eV at approximately 60 mol % InSb. The variation of optical energy gap with alloy composition at room temperature has already been shown in Fig. 11.1a. For alloys near the center of the composition range the energy gap reduces. Due to the smaller energy gap and larger carrier concentration these alloys become degenerate at room temperature and hence the Fermi level goes into the conduction band. Thus the actual energy gap for the compounds in the intermediate range may in fact be smaller than the measured value because of the Moss–Burstein effect. The bandgap bowing in alloy systems has been explained by virtual-crystal analysis [11.173]. The energy gap variation in InAs_xSb_{1-x} as a function of x is given as

$$E_g(x, T) = 0.434 - 0.771x + 0.59x^2 - 2.8 \times 10^{-4}T \text{ [eV]}. \quad (11.12)$$

Fig. 11.28 Room-temperature transmission spectra of InAs_xSb_{1-x} for various x values up to 0.6

Fig. 11.29 (a) Plots of absorption squared versus energy for $\text{InAs}_x\text{Sb}_{1-x}$. Straight lines imply a direct bandgap. (b) Temperature dependence of energy gap. Data fitted to equations of Bose and Varshni. Wieder and Clawson's formula is also plotted (after [11.176])

The absorption edge shifts to lower energy for $\text{InAs}_x\text{Sb}_{1-x}$ as x increases. The room-temperature transmission spectra for $\text{InAs}_x\text{Sb}_{1-x}$ as a function of x are shown in Fig. 11.28. The value of the energy gap was evaluated to be 0.17, 0.16, and 0.15 eV for $x = 0, 0.02$, and 0.05, respectively. The temperature dependence of the energy gap and free carrier absorption in a high-quality $\text{InAs}_{0.05}\text{Sb}_{0.95}$ single crystal were also studied between 90 K and 430 K through the absorption spectra [11.7] (Fig. 11.29a). The value of the energy gap at different temperatures along with the least-square fits to the above equation

as well as Bose ($E_g(T) = E_{g\text{BE}}(0) - 2a_B/(\exp(\theta_{\text{BE}}/T) - 1)$ [11.174, 175]) and Varshni ($E_g(T) = E_{g\text{v}}(0) - (\alpha T^2)/(\beta + T)$) equations are shown in Fig. 11.29b. The fits yield $E_{g\text{v}}(0)$, α , and β as 0.223 ± 0.003 eV, $7.1 \pm 2.3 \times 10^{-4}$ eV/K, and 675 ± 370 K, respectively. For $E_{g\text{BE}}(0)$, $2a_B$, and θ_{BE} the values are 0.214 ± 0.002 eV, 0.107 ± 0.01 eV, and 466 ± 46 K, respectively. It can be seen that the Bose and Varshni equations give nearly identical fits for $T > 125$ K (Fig. 11.29b). Below 125 K the Bose fit is better, as is usually the case. The value of $E_{g\text{BE}}(0)$ agrees with the relation $E_{g(0)} = 0.4324 - 0.8831(1-x) + 0.6853(1-x)^2$, which gives $E_{g(0)} = 0.212$ eV for 5 at. % arsenic. Through measurements on flash-evaporated films and using data from other groups, Wieder and Clawson [11.176] fitted the energy gap to the above equation. Owing to its inherent appeal and widespread use, this equation is also plotted in Fig. 11.29b, although the agreement is not good except at room temperature. Bansal et al. [11.7] showed that on the low energy side (< 100 meV) free electrons become the dominant source of absorption for $\text{InAs}_{0.05}\text{Sb}_{0.95}$. Due to the vast difference in strength, the contributions of band-to-band transitions and free carrier absorption (FCA) can be separated by a minimum in absorption which occurs at an intermediate energy. The temperature dependence of the absorption coefficient as a function of wavelength (14–25 μm) is shown in Fig. 11.30a. The studied sample was p-type at low temperatures and hence the FCA increased around RT when the sample became intrinsic and the Hall coefficient changed sign. Absorption below room temperature due to holes was too weak to be resolved from the higher-order interband absorption background because of their much larger effective mass. Using the value of the carrier concentration of this sample at 300 K, the FCA cross section was measured to be $7.35 \times 10^{-16} \text{ cm}^2$ at 15 μm . The curves in the figure can be fitted to a power law of the form $\alpha = k\lambda^p$. The experimentally determined value of the exponent p is ≈ 1.5 near room temperature and is the one theoretically expected for acoustic-phonon-assisted FCA. The FCA exponent shows a steady drop with increasing temperature above 300 K; several reasons have been given for this. Firstly, above 350 K, there is an enhanced probability for second-order interband transitions accompanying the abrupt increase in the optical phonon occupancy (optical phonon energy 300 K). These broaden the absorption edge by ≈ 25 meV and overlap with FCA, making the total absorption curve flatter and extraction of the exponent unreliable. Secondly, beyond 400 K, where the pho-

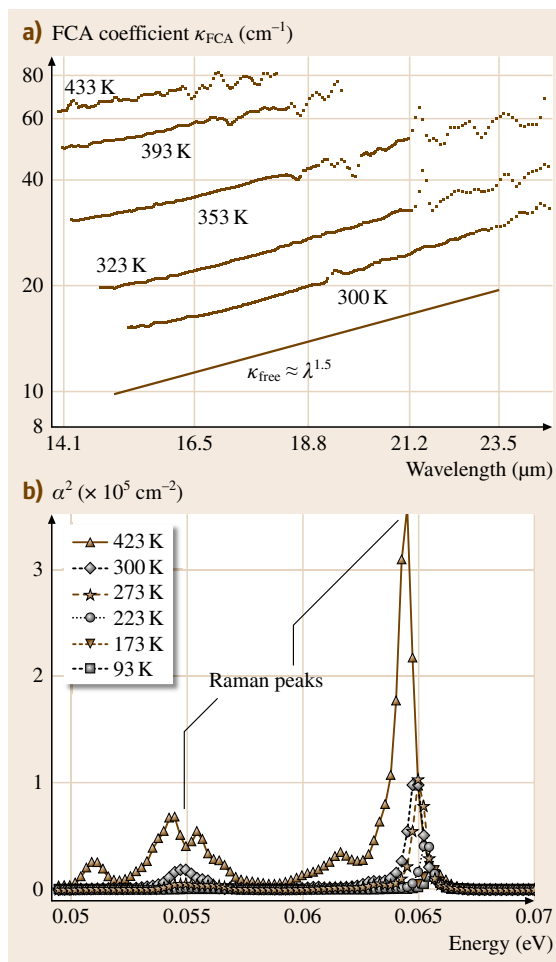

Fig. 11.30 (a) FCA spectra of $\text{InAs}_{0.06}\text{Sb}_{0.94}$ at different temperatures. Also $\kappa_{\text{FCA}} \approx (\lambda)^{1.5}$ is plotted for comparison (after [11.7]) (b) Raman peaks of $\text{InAs}_{0.06}\text{Sb}_{0.94}$ at different temperatures (after [11.5])

ton energy is $\approx 2k_{\text{B}}T$, classical analysis may become applicable. This, when accompanied by an increase in the optical phonon occupancy, could also lead to a sharp drop in the value of the relaxation time, τ , due to enhanced electron–optical phonon scattering. As τ reaches close to 10^{-14} s, deviation from the quadratic to a non-power-law behavior is expected, which could also lead to the observed reduction in the value of p . At high temperatures, multiphoton absorption by IR-active lattice modes is significantly enhanced. This is seen as noise in the high-temperature absorption spectra appearing around the second harmonic of the Raman peaks [11.177] (≈ 50 meV) (Fig. 11.30b).

$\text{InBi}_x\text{Sb}_{1-x}$

Quantum dielectric theory (QDT) has been used to predict the direct energy gap E_{g} of $\text{InBi}_x\text{Sb}_{1-x}$ semiconductor alloy up to 10 mol % InBi [11.39]. The calculated composition dependence of E_{g} for $\text{InBi}_x\text{Sb}_{1-x}$ is in good agreement with experimental results with a predicted semiconductor–semimetal transition (77 K) at $x = 0.124$. Figure 11.1b shows the E_{g} variation with InBi predicted using QDT for $\text{InBi}_x\text{Sb}_{1-x}$ at 0, 77, and 300 K, along with experimental results. E_{g} (77 K) values corresponding to 8–12 μm are obtained at $x = 0.043$ –0.070. The first-order calculation of E_{g} versus x follows the simple relation E_0 (eV) = $0.23 - 1.85x$ at 77 K. Vyklyuk and coworkers [11.149] have obtained the absorption coefficient of $\text{InBi}_x\text{Sb}_{1-x}$ in 0–10 eV range. The calculation of the absorption coefficient was based on the electron energy of $\text{InBi}_x\text{Sb}_{1-x}$ using a local empirical pseudopotential method with a virtual-crystal approximation including spin–orbital interaction. The energy dependence of the absorption coefficient of $\text{InBi}_x\text{Sb}_{1-x}$ showed an increase with Bi content and a shift in the absorption curve to lower energies [11.149]. The absorption edge of $\text{InBi}_x\text{Sb}_{1-x}$ at RT showed a shift towards lower energy [11.12]. Bandgap as estimated from the IR absorption edge is 0.113 ± 0.009 eV, which is very close to the value obtained from Fig. 11.1b [11.39]. They also noted that the free-carrier absorption was more in $\text{InBi}_x\text{Sb}_{1-x}$ crystal compared with InSb.

InSb, $\text{InAs}_x\text{Sb}_{1-x}$, and $\text{InBi}_x\text{Sb}_{1-x}$ Epilayers Grown on GaAs

Figure 11.27a,b also shows the absorption edge for InSb epitaxial layer at room temperature. The transmission spectra for the bulk and thin film are almost coincident, indicating that disorder effects are not strong enough to affect the optical absorption properties. Therefore, the effect of mismatched epitaxy is not evident in the optical absorption near the energy gap. This is in contrast to transport measurements, where heteroepitaxy was seen to be the most important factor affecting carrier mobility. Temperature-dependent optical absorption edge measurements on heteroepitaxial InSb are also shown in Fig. 11.27b. The difference in the cutoff energies between the spectra at 10, 80, and 300 K clearly shows the nonlinearity of the temperature dependence of the energy gap at low temperatures.

Figure 11.28 shows the transmission spectra measured for $\text{InAs}_x\text{Sb}_{1-x}$ with different alloy concentrations. As expected, the absorption edge clearly shifts to lower photon energies as the composition of arsenic

is increased. There is also an enhanced band tailing as the alloy fraction increases. Such band tails have been previously observed in similar anion-substituted mismatched alloy $\text{InP}_x\text{Sb}_{1-x}$ [11.178], and have been attributed to the formation of localized states as a result of composition fluctuations. It has been argued that composition and strain fluctuations effectively act as quantum wells which can trap electrons. A Gaussian distribution of their widths results in an exponentially decreasing density of localized states below the mobility edge. Recently, similar observations were reported by Gao et al. [11.179] on $\text{InAs}_x\text{Sb}_{1-x}/\text{GaAs}$ ($x < 0.06$) grown using ME. They also explain their results through composition fluctuations. Very recently Bansal et al. [11.180] further studied this and distinguished three absorption region: band to band, Urbach edge, and free-carrier absorption regions. They modeled the Urbach region and determined a structural disorder energy of 30 meV for $\text{InAs}_x\text{Sb}_{1-x}$. The RT energy gap for $\text{InAs}_x\text{Sb}_{1-x}$, calculated by assuming a cutoff at the mid-transmittance wavelength [11.181], is as low as 0.1 eV. However a more reliable estimation, i.e., fitting the absorption coefficient to the relation $\alpha = A(E_g - h\nu)^{1/2}$, gave a value of 0.133 eV for $\text{InAs}_{0.06}\text{Sb}_{0.94}/\text{GaAs}$. Wieder and Clawson's relation [11.176] gives the expected energy gap to be 0.146 eV for $x = 0.06$ at 300 K. Results for the bulk $\text{InAs}_{0.05}\text{Sb}_{0.95}$ sample showed perfect agreement with the above relation. Therefore, the 13 meV discrepancy is either due to error associated with calculating the energy gap (due to band tailing) or to a decrease in the gap due to residual strain. The residual strain, as evaluated from x-ray measurements, corresponds to a shift in the gap, $\Delta E = 2b(C_{11} + 2C_{12}/C_{11})e_{xx}$, where b is the deformation potential, C_{11} and C_{12} are the stress components, and e_{xx} is the in-plane residual strain, which is 0.0184 as evaluated from HRXRD. This yields a splitting energy (ΔE) of 15 meV, which may also explain the difference between the values for bulk and epitaxial $\text{InAs}_x\text{Sb}_{1-x}$. The change in E_g value with temperature for a $\text{InAs}_{0.06}\text{Sb}_{0.94}/\text{GaAs}$ sample along with fits to Varshni's and Bose–Einstein-type relations are also shown in Fig. 11.30. Varshni parameters for this curve are $E_g(0) = 0.193 \pm 0.007$ eV, $\alpha = 3.01 \pm 3.1 \times 10^{-4}$ eV/K, and $\beta = 341 \pm 60$ K. The Bose–Einstein fit yields $E_{g\text{BE}(0)} = 0.19$ eV, $2a_B = 0.051$, and $\theta_{\text{BE}} = 395$ K. The set of Varshni parameters are different from those obtained for bulk crystal. Marciniak et al. [11.182] have suggested a straight-line relationship between α and β , where $\alpha/(271 + \beta) = 6.5 \times 10^{-7}$ eV/K². Both the parameters

controlling the heat flow during growth, are 0.123 and $0.0474 \text{ W cm}^{-1} \text{ K}^{-1}$, respectively [11.185]. The specific heat of the melt and solid InSb are found to be 0.234 and 0.242 J/(g K) , respectively, and the latent heat of fusion of InSb is 108 J/g . Significant thermal param-

eters required for the growth are reported by Duffer et al. [11.94]. Dixon and Furdyna [11.186] reported the static dielectric constant of InSb lattice as 16.8 ± 0.2 . There do not seem to be detailed reports on the thermal properties of other considered alloys.

11.8 Applications

InSb and related crystals are used in many applications. Here we emphasize only infrared detector and galvanomagnetic sensor applications.

Infrared Photodetectors

The properties of InSb as a material for infrared detectors have been extensively discussed for more than 46 years now. At room temperature the intrinsic carrier density in narrow-gap materials is in the range $10^{15} - 10^{17} \text{ cm}^{-3}$ and the thermal generation rate is $10^{23} - 10^{24} \text{ cm}^{-3} \text{ s}^{-1}$. This results in a high noise level in photodetectors at room temperature. Ashley and Elliot [11.187] used *nonequilibrium* operation, which resulted in better detector performance at room temperature. The structure designed to achieve nonequilibrium (higher operating temperature) conditions is $p^+p^+\pi n^+$ or $p^+p^+\nu n^+$, where π and ν refer to intrinsic materials (either p- or n-type), which form an active region, and p^+ refers to wider-bandgap materials. The active region has a low doping level and therefore is intrinsic at RT. The n- and p-type contacts are made to the active region via regions with larger energy gap or higher doping level or both, so that under appropriate bias conditions minimal transport of minority carriers through the active region is ensured. At zero bias, the band structure of the devices ensures little transport of the minority carriers from the contact regions so that additional noise is minimized. The detectivity (D^*) of these devices is $2.5 \times 10^9 \text{ cm Hz}^{1/2} \text{ W}^{-1}$. For certain applications, particularly those requiring low temperature, it is often desirable to narrow the spectral responsivity, thereby increasing the detectivity by reducing the influence of background radiation. This can be achieved either by an external filter or by embodying the filter in the photodetector structure. Djuric et al. [11.188] made use of a remarkable technique which involves self-filtering based on the Moss–Burstein effect. The structure is an $n^+ - p$ -InSb photodiode (p-type InSb wafer and a heavily doped InSb layer using LPE). The quantum efficiency of the Moss–Burstein effect decreases almost linearly with wavelength. This allows approximately constant

sensitivity over a wide range of wavelengths when choosing appropriate material parameters. Later Bloom and Nemirovsky [11.189] concentrated on the fabrication of these detectors by reducing the surface recombination rates. Michel et al. [11.190] also developed InSb photovoltaic structures on GaAs using MBE and demonstrated a near-bulk value for the carrier lifetime in spite of large dislocation densities.

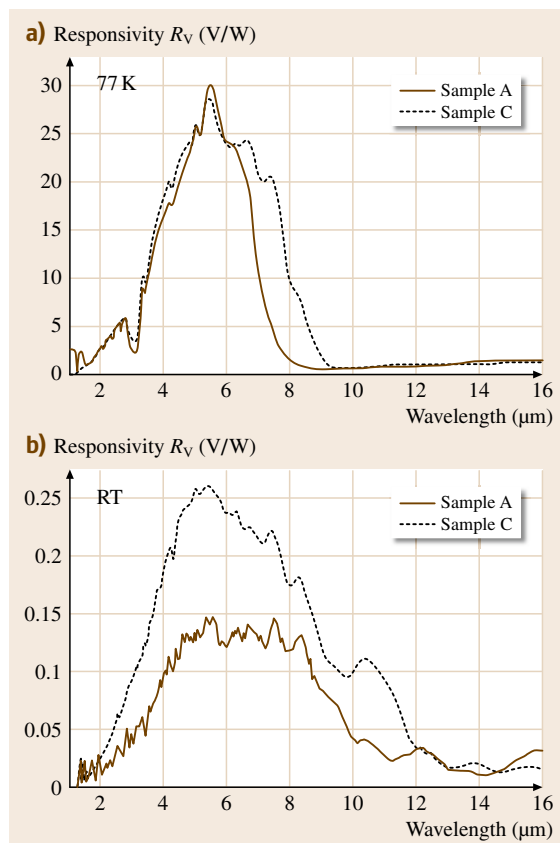

Fig. 11.32a,b Spectral responsivity of the photoconductors fabricated on InAsSb at (a) 77 K and (b) room temperature (after [11.34])

The highest carrier lifetime of 240 ns was reported for an InSb heteroepitaxial structure by these authors. InSb/InAs_xSb_{1-x}/InSb ($p^+ \pi n^+$) photovoltaic devices grown by LP-MOVPE and operated at room temperature in 8–13 μm was reported by Kim et al. [11.3]. Also, better performance was reported for photoconductors developed on p-InAs_xSb_{1-x}/p-InSb/GaAs [11.3]. Very recently Peng et al. [11.34] developed infrared photodetectors in the 8–13 μm range using LPE. They fabricated photoconductors from LPE-grown InAsSb/GaAs, and a notable photoresponse beyond 8 μm was observed at RT. In particular, for InAs_{0.3}Sb_{0.7}/GaAs, a photoresponse up to 13 μm with maximum responsivity of 0.26 V/W was obtained at RT (Fig. 11.32). Hence, InAsSb/GaAs heterostructures grown using LPE demonstrate attractive properties suitable for room-temperature, long-wavelength infrared radiation. Details of the detectors fabricated employing MBE and MOVPE can be found in [11.191, 192].

Galvanomagnetic Applications

The most common, semiconductor-based magnetic field sensors are silicon (Si)-based Hall sensors. In general, the higher the mobility of the semiconductor and the thinner the active region, the better the galvanomagnetic device. The room-temperature mobility of undoped InSb is ≈ 55 times higher than that of Si. Hence InSb should be preferred over Si for use in Hall sensors. In fact, bulk InSb wafers have been used for many years in the fabrication of magnetic field sensors, such as magnetoresistors and Hall sensors. Magnetic field sensors are, in turn, used in conjunction with permanent magnets to make contactless potentiometers and rotary encoders. This sensing technology offers the most reliable way to convert a mechanical movement into an electrical signal, and is widespread in automotive applications. Recent developments in the growth of thin epitaxial layers of InSb on semi-insulating GaAs substrates have resulted in the development of magnetoresistors with excellent sensitivity and operating temperatures up to 285 °C which are also cost effective. Hall sensors and magnetotransistors of thin n-InSb films outperform their Si-based counterparts even with integrated amplification. Oszwaldowski [11.194] also suggested very specific Hall sensors that can be made from heavily doped ($1\text{--}2 \times 10^{18} \text{ cm}^{-3}$) n-type InSb films. with these sensors they could achieve magnetic field sensitivity $\geq 0.05 \text{ V/T}$ and temperature coefficient of the output voltage $\leq 0.01\% \text{ K}^{-1}$, which are very difficult to achieve by any other Hall sensor. Heremans et al. [11.195] and Heremans [11.196] have described

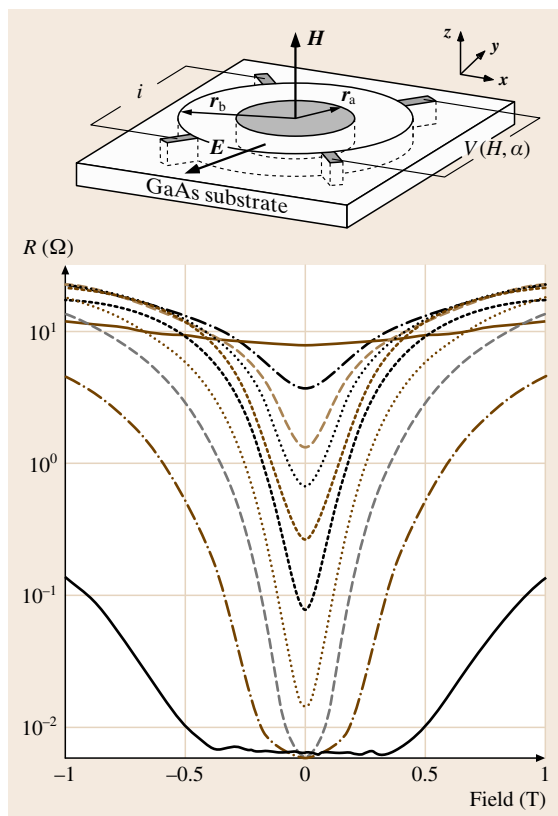

Fig. 11.33 RT resistance up to 1 T of a composite van der Pauw disk (vdP) of InSb and Au for a number of values of $a = 5r_a/r_b$. Inset schematic diagram of a cylindrical Au inhomogeneity (radius r_a) embedded in a homogeneous InSb vdP disk (radius r_b) (after [11.193])

device design criteria, materials requirements, and a direct comparison of the three types of galvanomagnetic devices, and have given the following guidelines for selecting sensors in different applications. According to them, NiFe-based magnetoresistors are preferred for sensing magnetic fields below 0.005 T, typical in magnetic read-out applications; Si Hall sensors with integrated amplification are useful in low-frequency applications in the field range of 0.005–0.03 T; and InSb-based magnetoresistors are most suitable in field ranges above 0.03 T but are not sensitive to the polarity of the field.

Recently Solin et al. [11.193] reported enhanced room-temperature geometric magnetoresistance in homogeneous nonmagnetic indium antimonide with an embedded concentric gold inhomogeneity (Fig. 11.33). The room-temperature geometric magnetoresistance is

as high as 100%, 9100%, and 750 000% at magnetic fields of 0.05, 0.25, and 4.0 T, respectively. They found that for inhomogeneities of sufficiently large diameter relative to that of the surrounding disk, the resistance

is field-independent up to an onset field ≈ 0.4 T, above which it increases rapidly. These results have been understood in terms of field-dependent deflection of current around the inhomogeneity.

11.9 Concluding Remarks and Future Outlook

In this chapter we have described and discussed certain specific characteristics of InSb, InSb-based ternary and quaternary crystals, and their thin films on highly mismatched semi-insulating GaAs substrates, with reference to infrared detection and galvanomagnetic applications. The use of these material systems as an alternative for such applications relies on the production of high-quality materials with low background doping level and defect density. While basic material quality is dictated by crystal growth conditions, the physical properties of the material are profoundly influenced by the process cycles and the conditions under which the devices are operated. Hence in making a good device, it is important to understand the material issues that are related to device performance and to achieve synergies between material preparation and device fabrication. Some of the issues which have been address in this review are:

1. How does mismatch heteroepitaxy affect the structural properties when the films are far beyond their critical thickness?
2. What do the interfaces look like?
3. Does strain modify the optical gap usefully?
4. How does the electron mobility depend on composition given that alloy scattering is negligible?
5. What role do dislocations play?

for which reasonable understanding has been provided.

It was found that scattering from dislocations, introduced as a result of GaAs heteroepitaxy, degrades mobility at low temperatures. However, room-temperature transport properties are comparatively unaffected. Bright-field cross-sectional TEM imaging shows a sharp interface with very small coalescing islands and the selected-area diffraction pattern indicates that the layer and the substrate are epitaxially oriented. Very similar results were obtained on $\text{InAs}_x\text{Sb}_{1-x}/\text{GaAs}$ and $\text{InBi}_x\text{Sb}_{1-x}/\text{GaAs}$ heterostructures. The energy gap of 0.133 eV for $\text{InAs}_{0.06}\text{Sb}_{0.94}/\text{GaAs}$ shows a 13 meV reduction due to residual strain. This reduction is very useful to shift

the energy gap to well within the 8–12 μm range. The interesting observation of band tailing as a result of alloying has been modeled through Urbach tail characteristics. Shubnikov–de Haas oscillations are observed in $\text{InAs}_{0.04}\text{Sb}_{0.96}$ and the effective mass of $\text{InAs}_x\text{Sb}_{1-x}$ for low values of x is reported. The temperature dependence of the energy gap and the behavior of free-carrier absorption have been reported for InAsSb alloy for a composition for which the energy gap is 15% lower than that of InSb. The values of fundamental material parameters, such as the zero-temperature gap and its temperature coefficients, the effective mass, etc., were evaluated and analyzed within the existing theoretical models. From the FCA spectra, it was concluded that, for 5% arsenic, alloy scattering is not the mobility-limiting mechanism near RT, which is useful for reliably modeling and evaluating the performance of optical and electrical devices made from these alloys.

Although successful reports on the growth of InSb, $\text{InAs}_x\text{Sb}_{1-x}$, and $\text{InBi}_x\text{Sb}_{1-x}$ crystals and their epitaxial films on semi insulating GaAs using liquid-phase epitaxy are presented in this chapter, a number of issues still remain to be addressed. In growth utilizing nonequilibrium techniques, whether one can increase the composition of As and Bi in single crystals of $\text{InAs}_x\text{Sb}_{1-x}$ and $\text{InBi}_x\text{Sb}_{1-x}$ remains to be explored. Reduction in the film thickness of these materials using LPE is another challenge which further opens the scope for improving heteroepitaxy of these materials. From structural, optical, and transport studies, it is clear that InSb–InAs and InSb–InBi alloying cannot be understood by simply using the conventional theories of alloy disorder.

A large electronegativity and size difference between the host and substituted anions also lead to considerable structural disorder in the form of local strains, defects, and at times compositional fluctuations. Thermodynamic analysis using empirical theories of bond energies can help to produce quantitative estimates of these effects. Such a calculation would be useful in determining the practical limits on the quality of samples grown under equilibrium conditions. $\text{InAs}_x\text{Sb}_{1-x}$,

$\text{InBi}_x\text{Sb}_{1-x}$, and $\text{InBi}_x\text{As}_y\text{Sb}_{1-x-y}$ are some of the many systems in the general class of highly mismatched alloys. A comparative analysis of other systems such as InPAs , InPSb , InNAs , and GaPSb over a wider compositional range would be useful in drawing generic conclusions regarding the properties of mismatched alloys. Experimental data on these systems are still limited. Shan et al. [11.197] have recently proposed a band

anticrossing model to explain the large bowing in dilute nitride systems. Since it is the only theory that can be rigorously compared against experiment, it would be interesting to look for the anticrossing gap in $\text{InAs}_x\text{Sb}_{1-x}$, $\text{InBi}_x\text{Sb}_{1-x}$, and $\text{InBi}_x\text{As}_y\text{Sb}_{1-x-y}$ if they exist. Such and other interesting issues, when properly addressed, will fix these materials firmly in the realm of modern technology.

12. Crystal Growth of Oxides by Optical Floating Zone Technique

Hanna A. Dabkowska, Antoni B. Dabkowski

Single crystals of various congruently and incongruently melting oxides have been recently grown by the floating zone (FZ) and traveling solvent floating zone (TSFZ) techniques. For the incongruently melting materials, the use of solvent with an experimentally determined composition allows the establishment of the *practical* steady state much faster, leading to better, more stable growth. Growth conditions for different oxides are compared. Important problems in crystal characterization and assessment of micro- and macrodefects are briefly presented.

12.1 Historical Notes

W. G. Pfann, a metallurgist at Bell Laboratories, developed zone refining, a precursor of floating zone crystal growth, in 1951. Pfann's process [12.1] involved placing the material to be crystallized in a crucible rather than suspending it in space as is the case in today's floating zone process. In 1952 Theurer, also at Bell Laboratories, created the floating zone process. Slightly later and independently, von Emeis at Siemens [12.2] as well as Keck and Golay [12.3] of the US Army Signal Corps developed a similar technique. Keck and Golay used *incandescent heating* with a short cylindrical tantalum heater rather than an optical system

and published their results in 1952. As Theurer's diary showed his priority in the invention, Bell Laboratories was eventually assigned a US patent [12.4]. According to Mühlbauer [12.5] the first firm to commercialize the float zone technique was Siemens in the early 1950s. They used the process in the course of manufacturing silicon, and patent for the technique known as the floating zone method was granted to them in 1953. They became the first company to produce ultrapure silicon single crystals for semiconductor devices by applying induction (radiofrequency, RF) heating to melt a narrow part of a cylindrical rod of polycryst-

talline material. Passing this molten zone along the rod transformed the ceramics into single crystals. In this case surface tension together with the electromagnetic force (*levitation*) supported the melt. The first company to manufacture a floating zone apparatus commercially was Ecco Corporation, North Bergen, NJ, in 1953.

The further development and production of float zone (FZ) silicon crystals took place in many countries. Detailed historical notes about the development of FZ technique can be found in [12.5]. Until the end of the 1950s, crystal diameter size did not exceed 25 mm, whereas during the 1960s and 1970s a dramatic increase from 33 to 50 and 75 mm was achieved. This diameter enlargement was a prerequisite for the development and fabrication of high-power discrete devices such as thyristors and others. The 100 mm crystal appears at the end of the 1970s, the 125 mm one in 1986, the world-wide first 200 mm (100) dislocation-free silicon crystal was grown at Wacker-Siltronic Company in September 2000.

Ferrites became important materials for microwave applications in the late 1950s and the floating zone tech-

nique was an obvious choice for crystal growth, but direct RF heating cannot be easily apply to oxides. Optical heating (*arc image furnaces*) utilizing carbon arc and elliptical mirrors was introduced for crystal growth of magnesium ferrite and sapphire by *De La Rue* and *Halden* [12.6] as a replacement for flame melting in the Verneuil method. His apparatus was based on earlier concepts and experiments with *image furnaces*, see *Null* and *Lozier* [12.7]. The concept of the image furnace was adopted to zone melting (in the geometry later call *pedestal growth*) for silicon by *Poplawsky* and *Thomas* [12.8] and soon *Poplawsky* applied this technique to ferrites [12.9]. The carbon arc heating is not an easy method to control, so at the same time the floating zone growth of yttrium iron garnet, $\text{Y}_3\text{Fe}_5\text{O}_{12}$ (YIG) was performed with RF heated MoSi_2 susceptor – which is also a kind of infrared (IR) optical heating – by *Abernethy* et al. [12.10]. As interest in ferrites was growing, soon more convenient halogen lamps and even more powerful xenon arc lamps were introduced and the apparatus for crystal growth of ferrites was developed by the groups of *Akashi* [12.11] and *Shindo* [12.12] in Japan.

12.2 Optical Floating Zone Technique – Application for Oxides

More recently the floating zone technique using halogen lamps and ellipsoidal mirrors (often called optical floating zone, OFZ) has been employed for crystal growth of a wide range of materials, including metals, oxides, and semiconductors [12.13–16]. With a growing number of optical systems around the world this technique is gaining popularity as the method of choice for the growth of various nonconventional oxides including high-temperature superconductors and new magnetic materials [12.17].

Crystals grown by the optical floating zone technique are of high quality but relatively small (usually not larger than a few millimeters in diameter and a few centimeters in length) so the majority of work is concentrated on new materials grown mainly for research purposes.

Recently high-quality crystals of $\beta\text{-Ga}_2\text{O}_3$ as large as 1 inch in diameter have been reported [12.18] but the only oxides grown by this technique for indus-

trial applications are still $\text{Y}_3\text{Fe}_5\text{O}_{12}$ [12.12, 14, 19] and TiO_2 [12.20].

In this chapter the advantages and disadvantages of the FZ technique for the growth of crystals of congruently and incongruently melting oxides and their solid solutions are discussed. For incongruently melting materials a variation of the FZ technique, called the traveling solvent floating zone (TSFZ), technique is used. Both methods are suitable for the growth of solid solutions.

The list of oxide materials grown by FZ and TSFZ methods includes simple oxides such as $\beta\text{-Ga}_2\text{O}_3$ or TiO_2 , as well as, complex oxides such as the spin Peierls material CuGeO_3 [12.17], high-temperature superconductors such as $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_n$ (BiSCCO) [12.17, 21], and frustrated antiferromagnets such as $\text{RE}_2\text{Ti}_2\text{O}_7$ (RE = rare earth) [12.22, 23].

The origin of most common macro- and microdefects – often seriously influencing crystal properties – is also briefly presented.

12.3 Optical Floating Zone and Traveling Solvent Crystal Growth Techniques

The idea of the optical floating zone is presented in Fig. 12.1. Two ceramic rods are mounted in such a way that their tips meet at the focal point of ellipsoidal mirrors. Halogen or xenon lamps of appropriate power sit at the other focal points of these mirrors. Any crystal growth process performed by the optical floating zone starts by melting the tips of polycrystalline rods, bringing them together and establishing a liquid called the *floating zone* between the bottom (seed) rod and a top (feed) rod (Fig. 12.2).

After the zone is created it starts moving upwards (either by moving the mirrors up or by moving the seed-and-feed setup down), the liquid cools and the material eventually crystallizes on the seed rod. During growth the rods rotate either in the same or in opposite directions with experimentally established rates. The rate of rotation is important as it is responsible for a pattern of forced convection flows within the zone and – as a result – for mixing of material, for the shape of the crystallization front (solid–liquid interface), and for the defects resulting from it. The rotation speed is optimized experimentally for each material and varies from 0 to 50 rpm. Successful growth requires a very stable zone. Stability of this zone depends on the quality of the starting rods as well as the alignment of both the feed and the seed rods. This is achieved by rigidly fixing the seed

rod to the lower shaft. The feed rod can either be attached equally rigidly to the top holder or can hang loosely from a hook. Rigid mounting requires a very high-quality (straight and dense) rod and a very precise alignment. Another important factor is the alignment of the lamp and mirrors. Mirrors are usually factory preadjusted, but alignment of lamps critically influences the temperature distribution within the zone.

It is advisable to start the growth on a crystalline, oriented seed, as this facilitates the beginning of crystallization and controls the appropriate orientation. It also prevents the soaking of the molten zone into the porous seed rod.

During the growth process only few parameters can be controlled. The pulling rate can be adjusted and this controls average growth rate. Due to the heat of crystallization this parameter also influence temperature near the crystallization front. The lamp power setting directly controls molten zone temperature, temperature gradients and also influences size and shape of the floating zone. The rate of rotation of both rods controls stirring of molten material which influence both, temperature distribution and composition within molten zone. Finally, adjusting the feeding rate controls the size of the zone.

There has been an intensive effort to model the silicon process [12.24, 25] but only a few modeling attempts have been made to understand what is happening inside the oxide molten zone [12.26–28]. The majority of modeling works deal with the floating zone method itself, investigating temperature oscillation in the zone [12.29], detailed lamp irradiation and thermal flows analysis [12.30, 31] or assessing the interface

Fig. 12.1 Schematic diagram of optical floating zone apparatus (A – atmosphere, Z – floating zone)

Fig. 12.2 Stages for nucleation on ceramic rods (see also Fig. 12.17)

Fig. 12.3a,b Convection flows in the molten zone. (a) Combined buoyancy and forced convection for counter-rotation. (b) Marangoni convection (after Brice [12.32])

shape [12.27]. The recent and most likely the most advanced three-dimensional (3-D) modeling, performed by Lan [12.28] for optical heating with two elliptical mirrors in the horizontal configuration, suggests that the temperature distribution is less symmetrical and that the pattern of convection cells is more complex than the one presented by Brice [12.32] in an older, simpler description of Si growth with RF heating. External heating (either optical or RF) causes significant overheating of the liquid zone surface. High temperature gradients in the molten zone lead to strong buoyancy as well as Marangoni convection [12.29]. If the feed and seed rods counter-rotate the convection patterns become even more complicated. To explain these patterns the existence of upper and lower convection cells has been suggested. A schematic explanation of convection flows in the molten zone is shown on Fig. 12.3. Because

the flows on the cells' interface should be collinear, one can expect only limited liquid exchange and – for incongruently melting materials – upper and lower cells having distinctively different chemical compositions.

Using growth of $\text{Y}_3\text{Al}_5\text{O}_{12}$ as an example of a congruently melting material (melting point, $\text{mp} = 1970^\circ\text{C}$) grown in a double elliptical mirror system, Lan [12.28] concluded that the overheating (above mp of the material) is higher than 600°C , with azimuthal differences of more than 400°C (in the plane of lamps) and a temperature gradient near liquid–crystal interface in the range of $1500^\circ\text{C}/\text{cm}$. As this model assumes no rotation, the realistic values of the temperature gradients as well as overheating with rotation will most likely be lower.

Very high thermal gradients, even with a small size of the liquid zone (typically 0.4 cm^3 for 0.7 cm rod diameter), cause fast convection flows. Indeed, the results of Lan's modeling suggest that the liquid velocity in the zone is in the range of up to a few cm/s .

In order to do the modelling one needs experimental values of material properties such as the surface tension, wetting angle, melt viscosity, and density as well as the optical properties, emissivity factor and thermal conductivity of the melt and the crystal. The change of these properties with temperature should be known as well. Although this information is available for $\text{Y}_3\text{Al}_5\text{O}_{12}$ [12.33], it is not yet available for the majority of oxides.

Due to experimental challenges and the high temperatures involved unfortunately it is not yet feasible to directly compare this modeling with experimental results.

12.4 Advantages and Limitations of the Floating Zone Techniques

The greatest advantages of the OFZ technique come from the fact that no crucible is necessary and that both congruently and incongruently melting materials can be grown. This allows for growth of large-sized crystals that was not possible before. The relatively high thermal gradient on the crystallization front characteristic of this method decreases the chance of constitutional supercooling and allows for faster growth of incongruently crystallizing materials (see the discussion in Sect. 12.7). It is also important to note that oxides with the highest melting temperatures can be grown using xenon lamps. The growth can be conducted at high pressure (up to 70 atm , depending on the furnace model) and in a controlled gas atmosphere. Solid solutions with controlled

and uniform chemical composition can be prepared because – in contrast to crucible methods – the steady state, in principle, can be achieved. This is beneficial for crystallization of incongruently melting materials and for doped materials (with distribution coefficient different than 1), as well as materials in which, due to cation substitution, the congruently melting composition is not stoichiometric. The floating zone technique, when supported by characterization methods such as differential thermal analysis (DTA) or/and x-ray diffraction, is also an effective approach for the construction and investigation of phase diagrams [12.15].

There are some limitations to the growth of crystals by the OFZ method. As a rule this method is not

suitable for materials with high vapor pressure, low surface tension or high viscosity as well as for materials that undergo a phase transition during cooling (because such crystals usually crack after growth) [12.34, 35].

The small volume of liquid in the zone makes the stability of this crystal growth method susceptible to fluctuations of power and/or short-time oscillations of

gas pressure. Together with very high thermal gradients at the liquid–solid interface this leads to difficulties in achieving and maintaining a flat crystallization front and stable growth rate, which can result in many defects and growth instabilities [12.36]. Significant thermal and mechanical stresses limit the size and quality of crystals obtained. This problem is reduced if an afterheater is applied [12.14, 37, 38].

12.5 Optical Floating Zone Furnaces

Several types of optical floating zone furnaces are commercially available on the market, with two [12.14, 39, 41] or four [12.15, 40] ellipsoid mirrors. The idea of the furnace using only one mirror was also tested in 1969 [12.11, 13]. All these furnaces employ halogen or xenon arc lamps of different power as an energy source and – as already mentioned before – the growth can be carried in a controlled gas atmosphere and/or at high pressure. Using high pressure is advantageous in the case of crystallizing materials with high vapor pressure at crystallization temperature. As the diffusion coefficient is inversely proportional to pressure, higher pressure will slow the vapor transport from the source

(the molten zone or its hottest regions) to the coolest part of the system (quartz tube). Furthermore, using gas with higher molecular mass (for example Ar instead of N₂) reduces the rate of evaporation. Additionally, the capability of FZ systems to apply high pressure is useful when high partial pressure of oxygen (p_{O_2}) is required to stabilize higher oxidation state of cation(s) and – as a result – crystallization of the appropriate phase. Oxygen pressure as high as 70 atm was used to growth of single crystals of ferrites [12.14] whereas for growth of layered cuprates application of O₂ stabilizes Cu²⁺ [12.17, 42, 43].

The main difference between the commercially available furnaces is that in one system the lamps

Fig. 12.4 Two (metallic) mirrors optical system of Nippon Electric Co. (now Canon). Mirrors are moved from their operational positions and the quartz tube is not installed for clarity of the view. M – mirrors, F – feed rod, S – seed rod, US – upper shaft, LS – lower shaft, TV – camera (after [12.39])

Fig. 12.6 Schematic drawing of a single elliptical mirror furnace (after Akashi et al. [12.11])

move (Crystal System [12.40]), whereas in the others (NEC [12.39] and URN2-ZN [12.41]) the rods move while the lamps stay in one position. In addition in the URN2-ZN apparatus the elliptical mirrors are configured in such a way that the optical axis of the system is vertical and the mechanical axis (of the rods) overlap. The single xenon lamp is at the focus of the lower mirror and the FZ at the focus of the upper one. This optical system is more complex and access to the growth chamber seems to be more complicated, but one gains a uniform azimuthal temperature distribution and less overheating of liquid.

Fig. 12.7 Schematic drawing of URM2-ZN design with vertical optical axis (after [12.41])

The practical, commercial realizations of OFZ are presented in Figs. 12.4 and 12.5 and drawings of other designs are presented on Figs. 12.6 and 12.7.

All of the furnaces are usually equipped with video cameras, allowing in situ observation of the crystal growth process during experiments. There are also options that allow for remote control of the process via the Internet. This is helpful for adjusting growth conditions during lengthy experiments.

12.6 Experimental Details of Ceramics and Rod Preparation for OFZT

Stability of the growth process – and the quality of the obtained crystal – depends strongly on the stability of the zone. This depends on the stability of the power and of the feed and seed rod shaft translations.

Modern equipment is capable of stabilizing the power supplied to the halogen lamp with relative accuracy better than 10^{-4} , and the rate of shaft translation is realized with similar accuracy. Stability of the gas pres-

Fig. 12.8 CoTiO_3 crystal (growth rate 1 mm/h) showing internal cavity caused by a stable bubble seriously interrupting growth

sure (and flow) is important for a constant temperature distribution as well, as even small fluctuations have to be avoided. Furthermore, achieving a stable liquid zone requires a homogeneous, uniformly dense ceramic rod acting as the source of material for crystallization. Gas bubbles incorporated into the feed rod can seriously influence the zone, interrupting the crystal growth process (Fig. 12.8).

Successful preparation of starting rods for crystal growth requires: muffle furnaces for preliminary ceramics preparation, furnaces with controlled atmosphere appropriate for rod sintering, a hydrostatic press, as well grinders and/or mortars, as the particle size after grinding is crucial for obtaining good-quality rods.

The first step in rod preparation is a typical ceramics synthesis. The batch of powders is weighed accordingly to the chemical reaction and is prepared by ball-mixing and then by manual or automatic grinding in the mortar.

Fig. 12.9a–c Steps for preparation of ceramic feed rods of $\text{SrCu}_2(\text{BO}_3)_2$: (a) sintered in air, (b) sintered in O_2 , (c) pre-melted in O_2

The powders are pelletized and annealed at an appropriate temperature and specific time. The quality of the prepared ceramics is assessed by x-ray diffraction and – if found to be acceptable – the material is reground and formed as a rod (typically 8–10 mm in diameter and 120–150 mm long) by either cold or hot pressing. The pressure has to be experimentally selected to avoid *over-pressing*, with the typical range being 800–2500 atm. Polyvinyl alcohol, glycerol or other common additives are often used to reduce internal friction during pressing, allowing the production of denser, less porous ceramic rods. The pressed rod is later sintered at an optimized temperature and appropriate atmosphere.

The density of as-obtained ceramic rods (Fig. 12.9) should be measured and compared with the crystallographic density. This ratio depends as much on the material as on the quality of preparation and varies dramatically from under 60 to above 90%. In many cases, when evaporation is not an issue it is suggested to premelt (grow very fast) a less dense rod before performing the final crystal growth. This was found to be especially important for slower-grown, incongruently melting compounds (e.g., high temperature superconductors (HTSC) or $\text{SrCu}_2(\text{BO}_3)_2$). In the furnaces mentioned above, crystals up to 100–150 mm long and 10 mm in diameter can be grown, but the typical size of a good-quality grown crystal is usually smaller.

12.7 Stable Growth of Congruently and Incongruently Melting Oxides

Differential thermal analysis (DTA) should be routinely performed for all (attempted) new materials to establish their melting properties. For many new materials this is often not possible as DTA apparatus rated above 1500 °C are not common and analysis at elevated tem-

peratures is often limited by a lack of appropriate crucible materials. In this case the melting properties are determined during preliminary growth. Depending on those properties either the direct crystallization or the traveling solvent zone (TSZ) approach is applied.

Fig. 12.10 Growth of congruently melting Al_2O_3 in an NEC furnace. Note *necking* on the lower part of the crystal

Fig. 12.11 Generic phase diagram of compound AB melting with peritectic decomposition

For congruently melting oxides the composition of ceramic rods, growing crystal, and the melt is the same. The crystal growth process in this case is relatively fast, and the growth rates vary from 1 to as high as 50 mm/h. Rods rotate in opposite directions so that temperature uniformity as well as mixing of material inside the molten zone is achieved (Fig. 12.10).

When an incongruently melting material (Fig. 12.11) is being grown one has to use a solvent (flux) to make

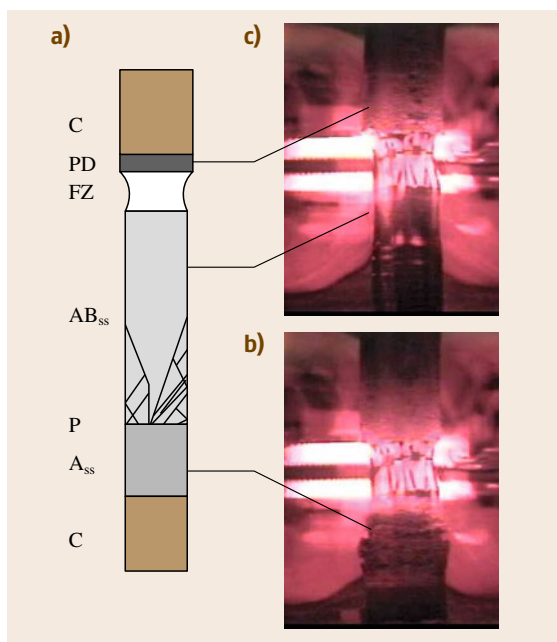

Fig. 12.12 (a) Simplified description of the creation of self-flux and growth of an incongruently melting oxide; C – ceramic rods with composition AB , A_{ss} – precipitation of phase A_{ss} . P – composition of liquid is passing peritectic point P, AB_{ss} – crystallization of AB_{ss} begins. FZ – floating zone, PD – peritectic decomposition of ceramic AB . On the beginning of growth primary phase A_{ss} crystallizes from FZ and liquid is continuously enriched in compound B until it reach peritectic composition P where AB_{ss} becomes primary phase solidifying with multiple nuclei. Grains with favoured orientation are growing faster and a single crystal of AB_{ss} can be grown. (b,c) growth of incongruently melting $\text{Ba}_x\text{La}_{1-x}\text{CuO}_4$ in a Crystal System furnace; image (c) recorded 23 h after image (b)

crystallization possible. The composition of the flux can be suggested on the basis of information from the appropriate phase diagram [12.44]. If this is not feasible it is suggested to use the self-flux approach. In such a case the zone is created by melting the ceramic rod (with composition similar to the composition of the required crystal) and carefully adjusting the temperature and growth speed until the evolution of the composition of liquid zone stabilizes growth with the required composition. In the case of peritectic transformation, the crystal growth starts with the precipitation of high-temperature primary phase on the seed rod (Fig. 12.12).

The zone composition then changes towards and beyond the peritectic liquid composition until a nearly

Fig. 12.13 Single crystal of incongruently melting $\text{La}_{2-x}\text{Ba}_x\text{CuO}_4$ grown by TSFZ technique (1 mm/h, 180 kPa O_2)

steady state is established and crystallization of the required phase begins. If the zone is quenched at this point it is possible to analyze the composition of the self-flux [12.45, 46].

In subsequent growths, to speed-up the process of achieving the nearly steady state, it is recommended to use a flux pellet with appropriate composition and size to create the molten zone. The flux pellet is synthesized and mounted between the feed and seed rods. As the temperature increases it melts and the rods become joined. At this point, the temperature has to be carefully adjusted again to allow for the establishment of a steady state, and then the growth starts. Dissolving the feed rod into the liquid in the zone continually restores the amount of material solidifying from the zone on the seed rod. The growth should be slow, due to the slow mass transport through the diffusion layer at the solid–liquid interface. For complex oxides such as $\text{Bi}_2\text{Sr}_2\text{Ca}_2\text{Cu}_3\text{O}_{10}$ [12.47] or $\text{SrCu}_2(\text{BO}_3)_2$ [12.48] it can be as slow as 0.1–0.2 mm/h, allowing crystallization of appropriate phase from a melt of significantly different composition.

Some materials decompose during growth and lose one of the components due to evaporation. In this case a small addition of the evaporating constituent to the feed rod proved to be successful (e.g., 1–1.5% CuO in $\text{Ba}_x\text{La}_{1-x}\text{CuO}_4$ [12.42, 49], see Fig. 12.13).

12.8 Constitutional Supercooling and Crystallization Front Stability

For complex oxides the congruently melting composition is quite often not exactly stoichiometric. This effect is well known for LiNbO_3 and was also observed for RE garnets (where the smaller RE ions usually occupying dodecahedral position also substitute smaller cations at octahedral positions). In such a case the evolution of the molten zone composition helps to produce crystals with composition close to stoichiometric. In the case of peritectic-type melting of binary (or more complex) compounds with solubility in the solid phase (i.e., with distribution coefficient $\neq 1$) the composition of liquid and solid in equilibrium are different (Figs. 12.11 and 12.12). Convection and/or mechanical mixing stir the majority of the volume of the liquid phase and this volume has a relatively uniform composition, but the layer in the vicinity of the crystallization front is nearly stagnant. This layer is depleted of the species that are incorporated into the crystal and enriched in those species rejected from the solid state. In contrast

to the volume of the well-stirred convection cell, mass transport in this layer is mostly driven by diffusion (*diffusion layer*) and a significant gradient of concentration is observed. For a distribution coefficient $k \ll 1$ this effect is more pronounced, and still more pronounced for the peritectic-type transition. As a result of this concentration gradient the solidus temperature decreases towards the solid–liquid interface. For lower thermal gradients in the diffusion layer a part of this layer can be supercooled more than liquid in close vicinity to the solid–liquid interface (Fig. 12.14), an effect referred to as *constitutional supercooling* [12.32, 50, 51].

As the growth rate is proportional to the degree of supercooling any positive fluctuation in the growth rate will lead to a further increase of growth rate (as it forces solid–liquid interface deeper into more supercooled liquid). The regions of the adjoining liquid will be even more depleted from crystal constituency and locally the solidus temperature will be even lower.

Fig. 12.14a,b Constitutional supercooling. **(a)** Concentration of dopant with distribution coefficient < 1 near the solid–liquid interface. **(b)** Conditions for constitutional supercooling near solid–liquid interface in the case of lower thermal gradient for temperature distribution $T_1(z)$

This causes crystallization front instability. Solute-rich channels form with the general direction parallel to the crystallization direction, which is not necessarily the pulling direction (note that both convex and concave crystallization fronts were observed in OFZ experiments) [12.52]. *Microfaceting* and *cellular growth* are often observed. For materials with high growth-rate anisotropy (especially for crystals with layered crystallographic structures such as CuGeO_3 [12.43] or $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_n$ [12.53]) this can result in platelike growth. Other defects such as flux tubes, precipitations,

and dendrite growth can also be expected as a result of crystallization front instability (Figs. 12.15 and 12.16).

To avoid constitutional supercooling the growth rate should be decreased. This measure reduces concentration gradients and the possibility of supercooling. Higher thermal gradients (on the solid–liquid interface) can also be suggested as a remedy. Unfortunately this action will cause even larger temperature gradients in the growing crystal, which can result in cracking during cooling (Fig. 12.15).

Control of the thermal gradient in the liquid near the crystallization front is a challenging problem. One

Fig. 12.15 Cut and polished slice of $\text{Dy}_2\text{Ti}_2\text{O}_7$ for defects observation. Transmission and dark field (crossed polarizers) macrophotographs

Fig. 12.16 Influence of evolution of composition of the molten zone on the crystallization process and defects in a *green sapphire* crystal grown by optical FZ. Al_2O_3 doped with $< 2\%$ of transition-metal oxides. Growth rate 8 mm/h in air, 25 rpm (counter-rotation). Transmission macrophotograph. (1) Initial part of growth. Nucleation begins on a ceramic seed rod with composition identical to the feed rod. The composition of molten zone is similar to that of the ceramic, resulting in low concentration of dopant in the crystal (*low coloration*). A multigrain crystal evolves into a single crystal after necking. Thermal stress during cooling causes cracks in the multigrain region. (2) Beginning of single-crystal growth. The concentration of dopant in the molten zone increases, as does the concentration of dopant in the crystal (*green coloration*). Isolated precipitations are seen as *dark spots* elongated in the growth direction (*white vertical strips* are caused by light reflection inside crystal). (3) Central part of the growth. The concentration of dopant in the solid (*greener coloration*) increases as a result of significantly higher accumulation of dopant in the molten zone. The density of precipitations increases due to more severe constitutional supercooling conditions. Note the striations, related to growth rate instability. These striations visualize a nearly flat crystallization front. (4) Advanced part of the growth. The concentration of dopant in the solid (*more green*) is higher due to the accumulation of dopant in the molten zone. This relative increase of dopants is lesser than observed in the lower part of crystal showing a tendency to stabilize. The density of precipitations is high. (5) The final part of the growth crystal growth termination. The crystal grows faster for a brief period of time and then the molten zone solidifies quickly (paraboloid tip). The fast growing part has a high density of precipitates and higher dopant concentration (*very green*). Very high concentration of dopant (and defects) is present in the solidified tip; this part of boule crystal is opaque ◀

of the possible approaches – anisotropic heating – was successfully applied by Watauchi et al. [12.54] for growth of congruently melting CuGeO_3 and incongruently melting $\text{Sr}_{14}\text{Cu}_{24}\text{O}_{41}$.

These effects are also depicted in Fig. 12.16. Single crystals of *green sapphire* (Al_2O_3 with $< 2 \text{ mol } \%$ of transition-metal oxides added, dopant segregation coefficient < 1) have been grown with constant pulling rate and dopant accumulate in the FZ as growth

progress. As the concentration of dopant increases, so does the degree of constitutional supercooling, creating increasing amount of defects. As the growth was not long enough the *steady state* could not be achieved (as it is an asymptotic process), but coloration of the upper part of the crystal indicates that as the crystal grows the dopant concentration apparently stabilizes – in contrast to the crucible methods.

12.9 Crystal Growth Termination and Cooling

As most of the heat is supplied to the crystal via the liquid zone, growth termination generates difficult-to-avoid *thermal shock* to the crystal. To lower the thermal shock the tip of as-grown crystal should be left in the hot zone during the lamp cooling process. The rate of lamp cooling should be related to the growth rate as switching off the lamps rapidly results in cracks in the crystal.

In some cases, it is advisable to relax the stresses created during the growth and cooling process by annealing the as-grown crystal at elevated temperature, then cooling it slowly to room temperature. After growth, annealing in a specific atmosphere often helps to reduce the number of defects present [12.51].

12.10 Characterization of Crystals Grown by the OFZ Technique

A good crystal – as defined by the *end user* – is in fact a crystal sample optimized for measurements or analysis by a particular method. Such a sample is usually oriented and cut to the required size. Special preparation of the surface of the crystal may also be necessary.

Large single crystals of silicon grown by the FZ method are of extremely good quality and can be dislocation free, but even they are not perfect as they have striations, oxygen incorporation, and other minute defects that influence or limit some demanding applica-

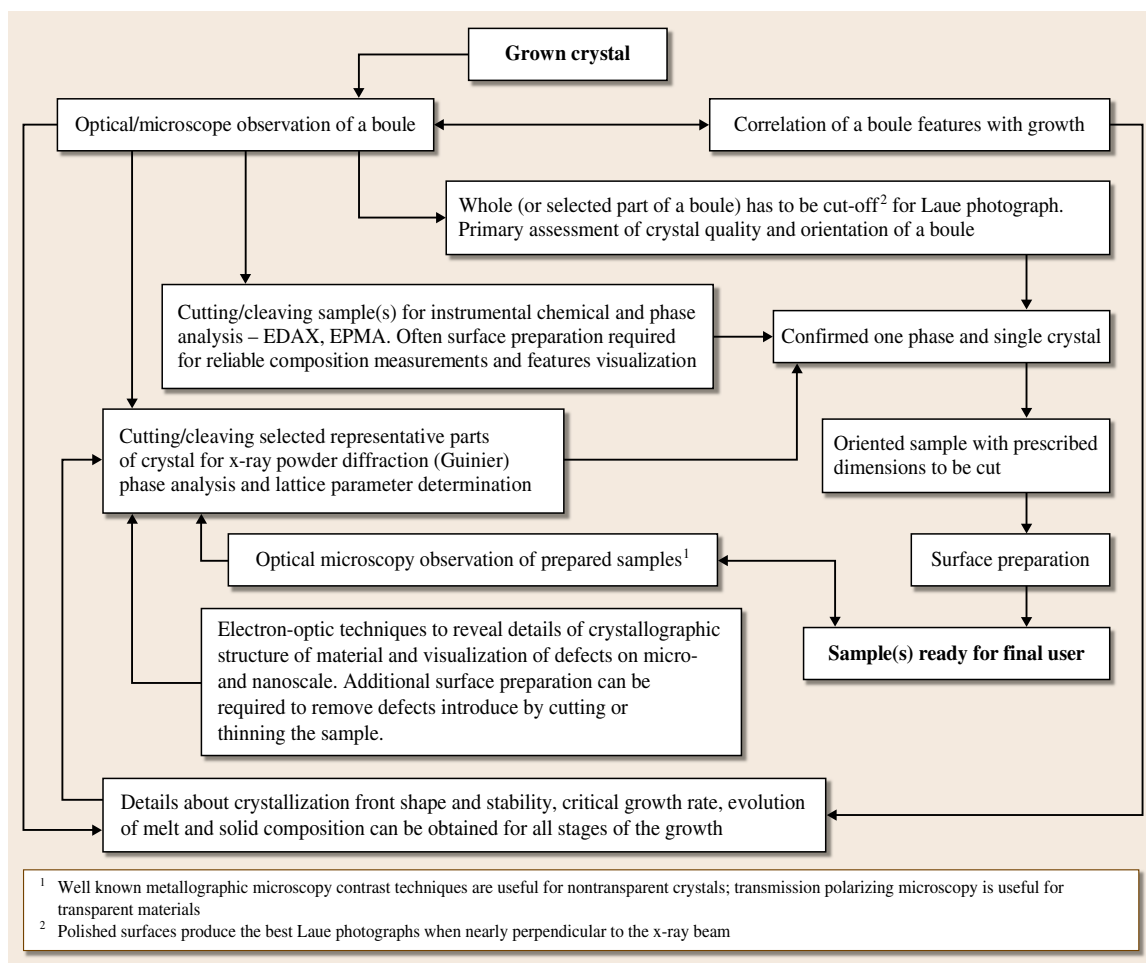

Fig. 12.16 Experimental approach to characterization of crystals grown by optical floating zone techniques

tions [12.55]. Improving the quality of a substantial size crystal in real life is a challenging and time-consuming task. It is mostly driven by specific applications or user demands – the silicon with its steady improvement is the best example.

Oxide crystals grown by OFZ method are not an exception to this rule and a lot of time and effort has been spent perfecting them. The more complicated the chemical formula of the attempted material, the more time is required to grow high-quality (although still not perfect) single crystals.

Careful characterization of both preprepared ceramics and the resulting crystals is essential for producing high-quality materials for further applications. This characterization depends as much on the material itself as on the purpose of its production.

Full characterization of a crystal involves a lot of time and manpower and is rarely performed. As growers using floating zone technique are interested mostly in investigating specific effects (e.g., superconducting properties) they often neglect detailed characterization of the crystals obtained. Even more unsettling is the fact that reviewers of renowned journals accept works done on crystals with virtually no characterization mentioned. This creates a vicious circle, as a generation of students believes that anything grown is a single crystal. Figure 12.16 suggests the basic experimental approach to characterization and quality improvement of crystals grown by the OFZ technique.

The existence of the required phase is usually confirmed by x-ray powder diffraction. Powder diffraction

Fig. 12.17 Cross section of the initial part of $\text{Sr}_{14}\text{Cu}_{24}\text{O}_{41}$ crystal grown at 1 mm/h in 8 atm O_2 . Note the visible grain boundaries on the axial cross section and a core on the cross section perpendicular to the boule axis

also allows the assessment of the uniformity of the material and addresses the problem of the existence of more than one phase. Accurate values of crystallographic lattice parameters can be measured by a Guinier camera with either Si or KCl as the internal standard, using a minute amount of material cut or cleaved from selected, characteristic parts of a boule. This information is important when crystals of solid solutions are obtained.

The observation of an as-grown transparent boule under an optical and/or polarizing microscope can reveal different defects in the crystal and their evolution during the growth process. It can also monitor the continuity of the growth and facilitate the observation of how changes of growth conditions (applied power, growth, and feed rate as well as speed of rotation) influence the quality of material grown (Fig. 12.17).

For nontransparent materials the surface features often mask the volume ones. This makes orientation of an as-grown FZ crystal very challenging. The majority of crystals grown by OFZ technique do not show distinctive facets (due to the high thermal gradients); usually they are round or oblong in cross section (Figs. 12.17 and 12.18). In this case sectioning of a grown boule and special surface preparation such as polishing and chemical etching are necessary before orientation by x-ray methods.

If as-grown crystals show distinctive facets then the facet quality may indicate overall crystal quality, and their shape and the angles between them as well as optical properties of materials can be used to orient the crystal. The existence of facets suggests a convex interface and can also be connected to growth striations. X-ray topography, discussed in detail in [12.56], con-

Fig. 12.18 Single crystal of $\text{SrCu}_2(^{11}\text{BO}_3)_2$ grown at 0.25 mm/h in 280 kPa (abs.) O_2

firmed a compositional difference between faceted and nonfaceted regions for YIG crystals [12.13, 57].

The Laue photography technique is a versatile method for crystal orientation (especially with available software [12.58]) and can also provide a preliminary assessment of the as-grown rod quality, answering the basic question of whether the material is a single crystal, multigrain sample (*blocks*) or polycrystalline boule with some degree of texture, etc. As the penetration of x-rays is in the micrometer range, the confirmation of crystallinity of a whole boule requires multiple Laue photographs (Fig. 12.19). If the Laue technique is used to assess local crystal quality, which relies on visual analysis of the shape of diffraction spots, its sensitivity is considerably limited and produces qualitative results only. For crystals of high quality collecting a *rocking curve* (ω -scan, which allows us to determine the full-width at half-maximum, **FWHM**) or pole figures using multiaxis diffractometers (preferably on polished and chemically treated

Fig. 12.19 Two grains in $\text{SrCu}_2(\text{BO}_3)_2:\text{Mg}$ crystal. Regions marked A have nearly identical crystallographic orientation, but different from that in regions marked B, which are also co-oriented (characterization by Laue photography, courtesy of S. Dunsiger)

Fig. 12.20 Single crystal of $\text{Sr}_{1.95}\text{Na}_{0.05}\text{Cu}_2(^{11}\text{BO}_3)_2$ grown at 0.25 mm/h in 280 kPa (abs.) O_2

surfaces) addresses problems related to mosaic spread, grains, and twinning in a more quantitative manner. The rocking curve method can also be used for neutron diffraction [12.59].

Solving crystallographic structure provides the ultimate description of the crystal. Single-crystal x-ray diffraction is performed on a selected, small (and usually perfect) piece of as-grown material and consequently does not provide information about the entire grown crystal.

Both x-ray and electron diffraction provide very valuable surface information. Neutrons, on the other hand, provide information about the entire volume of the crystal due to their low absorption by the majority of materials. Neutron diffraction techniques – if available – provide an excellent confirmation of the total crystal quality because all the substantial grains present in the as-grown crystal can be detected. This

is especially important in the case of nontransparent crystals where the assessment of the quality of the whole boule can be performed without labor-intensive and destructive sectioning, surface preparation, etc. For example, high-resolution, elastic neutron scattering measurements on $\text{SrCu}_2(^{11}\text{BO}_3)_2$ confirmed that slowly (less than 0.3 mm/h) grown crystals (Fig. 12.18) are a single domain each, with a mosaic spread of the (110) Bragg peak of 0.3° . Note, that in this case, to avoid high thermal neutrons absorption in ^{10}B ($\approx 20\%$ of natural abundance) ^{11}B isotope enriched to 99.6% has been used [12.60].

Similar analysis performed on $\text{Sr}_{1.95}\text{Na}_{0.05}\text{Cu}_2(^{11}\text{BO}_3)_2$ (Fig. 12.20) revealed the presence of 11 grains in similarly sized crystal grown in the same conditions.

Energy-dispersive x-ray analysis (EDAX) and electron microprobe analysis (EPMA) can confirm the exact chemical formula of crystals and solid solutions grown in different conditions. They also allow advanced phase analysis of obtained materials. Good oxide standards are essential for quantitative analysis.

Single crystals of oxides are generally investigated by the crystal users, according to physical properties and predicted applications. Investigation of these properties and their changes with different dopants and growth conditions are now the main purpose of growing crystals by OFZ and TSFZ methods. The majority of crystals grown for research purpose have unique magnetic, electrical, and crystallographic properties, which are investigated and reported in specific journals.

12.11 Determination of Defects in Crystals – The Experimental Approach

All crystals contain defects and impurities that influence their physical properties. To observe and assess the growth features an oriented crystal has to be cut and polished. Which defects are expected determines the way in which the sample is prepared for observation (Figs. 12.15–12.19). It should be specified what defects are expected in crystals grown by a given method, as many defects interfere with measurements and applications.

An excellent discussion of the defects present in oxide crystals grown from low-temperature solutions is given by Rudolf [12.61], from high-temperature solutions by Elwell and Scheel [12.50], and for oxides grown by Czochralski method by Hurle [12.51].

The defects present in oxide crystals grown by the optical FZ technique are similar to those found in crys-

tals grown by other methods, but some result from the specific growth conditions in the OFZ, such as the very high temperature gradients (for both FZ and TSFZ methods) and growth from flux (for TSFZ method). In the next paragraph those defects and the reasons for their appearance are discussed.

Increasingly available and advanced electron-optics techniques with easily accessible instrumentation such as scanning electron microscopy (SEM), transmission electron microscopy (TEM), high-resolution transmission electron microscopy (HRTEM), electron energy-loss spectroscopy (EELS), and high-angle annular dark field in scanning transmission electron microscope (HAADF-STEM) answer many questions related to the real structure of crystal and the presence of defects on the scale from millimeters down to atomic

Fig. 12.21 *Top*: Single crystal of BiSCCO 2212 grown by TSFZ technique. *Left*: plates cleaved from this crystal. *Right*: HRTEM image of the (100) plane with grain boundary at the center. The arrows in the image indicate the direction of the *b*-axis in each grain (courtesy Y. Zhu) ►

resolution. Additional sample preparation is necessary to fully utilize the potential of these techniques. A leading experimental work on defect characterization, using STEM, EELS, and TEM techniques on cleaved $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_n$ crystals grown slowly (0.21 mm/h) by TSFZ method (Fig. 12.21) has recently been published by Zhu et al. [12.62].

Figure 12.22 presents a comparison between known crystallographic structure and a HAADF-STEM image. This very sophisticated method of characterization of crystal grown by TSFZ method visualizes the displacement of Bi atoms in crystallographic lattice by intensity modulation; the results are consistent with (but much clearer than) those obtained with conventional high-resolution TEM on the same crystal sample. Figure 12.23 shows a detailed analysis of grain boundary performed on a HAADF image. The line defect has a lattice parameter suggesting that it is an intergrowth of Bi-2201 phase in Bi-2213 crystal. Stacking defects are characteristic for BiSCCO superconductors and other

layered compounds, but it is common to find few hundred by few hundred nm area of the perfect atoms arrangements – see Fig. 12.24 in the crystal of $(\text{La}, \text{Ba})_2\text{CuO}_4$ grown by TSFZ.

Local macrodefects (already mentioned in the section about instabilities in crystal growth), i.e., *microfaceting* (Fig. 12.20) and *cellular (grain) growth*, as well as *grain boundaries* (Figs. 12.12, 12.17, and 12.25), *flux tubes*, *precipitations*, and *dendrite growth* [12.62, 63] are all present as a result of crystallization front instability. They are often observed under

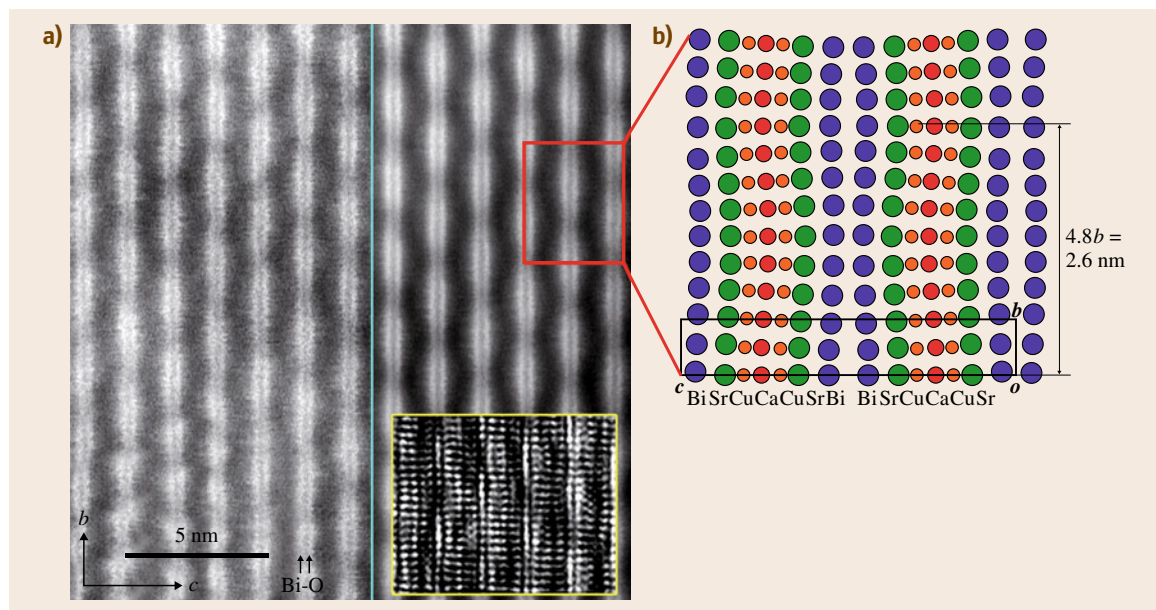

Fig. 12.22 (a) High-resolution HAADF image of Bi-2212. The double bright fringes correspond to Bi-O bilayer and dark ribbons to atomic layers of lighter elements. Compared with model of Bi-2212 incommensurate modulated structure (b) (after [12.62], courtesy Elsevier 2006)

Fig. 12.23 HAADF images of BISCCO-2212 with intergrowth of 2201 phase. *Yellow profile*: calculated lattice parameter c ; over the intergrowth $c = 25.5 \text{ \AA}$, indicating that this defect is an intergrowth of 2201. *Blue profile*: normalized Ca signal related to the local concentration of Ca, indicating absence of Ca in this layer (after [12.62], courtesy Elsevier 2006)

polarizing microscope and/or by x-ray topography. These defects are more pronounced at the beginning of crystallization and can also be eliminated with the

Fig. 12.24 HRTEM of perfect crystal of $\text{La}_{1.9}\text{Ba}_{0.1}\text{CuO}_4$ grown by TSFZ method (image courtesy of G. Botton and C. Maunders)

Fig. 12.25 Macrograph of polished cross section of La_2CuO_4 crystal grown 1 mm/h on seed, with visible large grains (polarized light, false colors)

use of a crystalline (preferably oriented) seed and/or necking procedure (Fig. 12.10). Crystal quality can be further improved by adjusting the rotation so as to maintain a flat crystallization front and slower growth rate.

Impurities, inclusions, and precipitates (e.g., in $(\text{La}, \text{Sr})_2\text{CuO}_4$ [12.63] or YVO_4 [12.64, 65]) are particles of the same or different phases embedded into otherwise good crystals. They can be generated by instabilities in the growth conditions leading to a noticeable amount of undissolved material in the molten zone. A slight change in stoichiometry of the starting rod can sometimes result in inclusion-free crystals as was proved for crystals of Mg_2TiO_4 grown from ceramic rod with $\text{Mg} : \text{Ti}$ ratio of $2 : 1.01$ [12.46]; a small excess of CuO is also used for various cuprates [12.21, 66, 67]. Dense feed rods and slower growths have been suggested for reducing the number of inclusions. Inclusions – on their own – are also the main cause of dislocations. The number of *precipitates* (such as the presence of Al_2O_3 in NiAl_2O_4 [12.52] or carbonates and BiO_x phase detected in $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_n$ [12.62, 68]) can sometimes be reduced with a slower growth rate or change of growth atmosphere.

Cracks, caused by mechanical stress due to cooling (e.g., in $\text{Ca}_2\text{Al}_2\text{SiO}_7$ [12.69] or SrZrO_3 [12.70]), can be diminished with the use of an afterheater [12.70, 71]. Sometimes, severe cracks are the result of phase transitions during cooling (e.g., CaTiSiO_5 , Fig. 12.26). Change of the growth atmosphere (from air to N_2) proved to be helpful in the above case [12.35].

Fig. 12.26 CaTiSiO_5 undergoes phase transition during the final stage of cooling (about 235°C). Initially transparent crystal cracked only when cooled to near room temperature; H. Dabkowska, A. Dabkowski, unpublished results

Gas bubbles are trapped inside crystals grown by the FZ method because the shape of the solid–liquid interface causes the bubbles to concentrate in the core region of the crystals (Fig. 12.8). This effect is often caused by either solubility of O_2 in the liquid phase or partial decomposition of oxides. It can be controlled to some extent by atmosphere composition, as described for Al_2O_3 [12.72, 73] and Li_3VO_4 [12.74].

Striations are caused by fluctuations of the temperature of the liquid near the crystallization front, originating from convection flows. Temperature fluctuations cause fluctuations of the growth rate, and as a result there are changes in chemical composition (as the effective segregation coefficient depends on the growth rate). Striations may be used as indicators of the shape of the solid–liquid interface [12.13, 65]. Optical

observations on polished and etched YIG revealed the internal structure of a crystal, providing valuable information about the growth mechanism [12.12]. This proved that too fast a growth rate leads to *cellular growth*, which can often be corrected by lowering the growth speed.

Sheet defects [12.15, 17, 54] and *eutectic solidification* can be revealed by careful observation of the cross section of as-grown crystal when the coexistence of two or more phases is noticed. Mao et al. [12.75] combined microscope observation of polished Sr_2RuO_4 crystal with x-ray Laue photography and detected the presence of layered intergrowth of different phases (Sr and SrRuO_3) in the crystal. On the basis of this analysis it was possible to optimize the starting composition of the feed rod and the growth conditions, reducing the level of impurities and defects and increasing the T_c of ruthenate. Sometimes it is possible to understand and modify the physical properties of material by identifying defects resulting from the crystal growth. For example, eutectic solidification in crystals grown by OFZ was discussed by Troileux et al. in $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$ [12.76] and by Fittipaldi et al. [12.77] in the Sr–Ru–O system.

Twin boundaries analyzed by x-ray diffraction depend mostly on the crystallographic structure of the material (e.g., $\text{Mg}_3\text{V}_2\text{O}_8$ [12.78] and $\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$ [12.79]).

The influence of convection on dopant segregation is discussed in [12.36, 80, 81].

12.12 Details of Conditions for Growth of Selected Oxide Single Crystals by OFZ and TSFZ Methods

In Table 12.1 examples of oxides grown by FZ and TSFZ techniques and the growth conditions employed are listed. Crystals grown with the application of a sol-

vent are marked with a dagger, and references referring to defects in each oxide crystal are marked with an asterisk.

Table 12.1 Examples of oxide crystals grown by optical floating zone technique and traveling solvent optical floating zone technique (marked by †). References discussing defects in obtained crystals are marked by *

12.13 Conclusions

The field of crystal growth by the optical floating zone and traveling solvent floating zone techniques is definitely expanding. With a growing number of highly computerized furnaces the quality and amount of works reported on new and already known materials is rising. The main advantage of both discussed floating zone techniques lies in the high purity of the obtained crystals resulting from the absence of a container. This feature also allows us to melt and grow high-quality, relatively large and uniform crystals of oxides for which there is no container (crucible) – either because of very high melting point or the melt being very aggressive – and which cannot be obtained by other methods. Both of these methods also make it possible to prepare solid solutions of oxides, modifying their properties according to the future applications.

Numerical modeling of the floating zone silicon process has turned out to be an excellent tool for modern crystal growth practice. Chains of models that cover the complete floating-zone process have been developed over the years [12.24, 25]. Now it is possible to simulate numerically the growth situations precisely enough to improve the final crystal quality even for very large diameters. Further modeling efforts, especially for other materials for which it is possible to compare modeling predictions with experimental observations, are necessary to improve the understanding of transport processes in the molten zone and of heat transport in

the whole system. Only then will it be possible to explain the changes observed in growth features as growth conditions change.

Apart from crystallizing new materials, future work in this area should also include:

- Investigation of phase diagrams
- Understanding/assessing high-temperature properties of molten oxides and salts
- Creating a user-friendly theoretical approach connecting crystal growth conditions with obtained results.

There is also the crucial but nearly untouched problem of automation of crystal growth. The automatic diameter control systems have proven to be useful in the Czochralski crystal growth of oxides [12.51] and one can expect that this approach can be successfully applied to grow them by the optical floating zone process as well.

It took about 50 years of research and financing to grow very high-quality, large single crystals of single element Si by FZ technique. Now the challenge is to follow this with growth of other technologically important materials. To achieve this continuous cooperation between a crystal grower and crystal user is necessary. Without good characterization of the crystals grown no progress in crystal growth can be achieved.

13. Laser-Heated Pedestal Growth of Oxide Fibers

Marcello R.B. Andreetta, Antonio Carlos Hernandez

The laser-heated pedestal growth (LHPG) technique, when compared with conventional growth methods, presents many advantages, such as high pulling rates, a crucible-free process, and growth of high and low melting point materials. These special features make the LHPG technique a powerful material research tool. We describe the background history, theoretical fundamentals, and how the features of LHPG affect the growth of oxide fibers. We also present a list of materials processed by laser heating in recent decades, such as LiNbO_3 , Sr-Ba-Nb-O , $\text{Bi}_{12}\text{TiO}_{20}$, Sr_2RuO_4 , Bi-Sr-Ca-Cu-O , $\text{ZrO}_2\text{:Y}_2\text{O}_3$, LaAlO_3 , and also the eutectic fibers of $\text{Al}_2\text{O}_3\text{:GdAlO}_3$, $\text{Al}_2\text{O}_3\text{:Y}_2\text{O}_3$, and $\text{ZrO}_2\text{:Al}_2\text{O}_3$.

Laser technology has been applied for many years to process a wide range of materials and devices. The characteristics that make laser radiation very attractive for this purpose are its coherence and collimation, which allow the adjustment of the energy distribution with conventional optical elements as well as location of the heat source outside the preparation chamber. The main applications of laser materials processing technology are: perforation, cutting and welding, sintering, surface thermal treatment, unidirectional solidification applied to fiber pulling, material texturing, and production of aligned eutectic materials.

Among all the laser-heated crystalline fiber-pulling techniques that have appeared over the last 40 years, laser-heated pedestal growth (LHPG) has become one of the most powerful tools in new and conventional materials research. The main advantages of this technique are its high pulling rates (about 60 times faster than

conventional Czochralski technique) and the possibility to produce very high melting point materials. Besides that, it is a crucible-free technique, which allows the pulling of high-purity single crystals and composite fibers, avoiding mechanical stress and contamination due to the crucible material during the solidification process.

In addition to all of these advantages of the LHPG technique, the crystal geometric shape, its flexibility for small diameters, and its low cost make single-crystal fibers (SCF) produced by LHPG even more suitable to substitute for many of today's bulk devices, especially with respect to high melting point materials. However, for this purpose the SCF must have equal or superior optical and structural qualities compared with bulk devices.

In this chapter we describe the laser-heated pedestal growth technique as a powerful materials research tool

and its features, such as the high axial thermal gradients at the solid–liquid interface. In order to produce this chapter, the authors analyzed more than 300 original scientific papers dealing with laser-heated pedestal growth. The publication dynamics on laser-heated fiber growth using the laser-heated floating-zone-like technique are presented in Fig. 13.1. Those are the results of the last two decades of research. From these data we can verify the great increase in publication rate over the last two decades, showing the importance of this technique in materials science. We also present the historical evolution, theoretical fundamentals, and how the unique features of the LHPG technique affect the quality of the pulled fibers and make it possible to pull incongruently melting and evaporating materials, as well as its influence on the microstructures of eutectic oxide composites.

13.1 Fiber-Pulling Research

The first publications on fiber preparation from the melt date back to the beginning of the 20th century and were restricted to research on metal wires. The origin of this research started with the physicists *Baker* [13.1] and *da Costa Andrade* [13.2], who wrote in his personal reminiscences: “I continued my work on the creep of metals and accidentally made the first single crystal metal wires” [13.3]. However, in the same period, there was also the need to understand one of the topical areas of physical chemistry that had lasted for 50 years: the measurement of crystallization velocities [13.4,5]. It was with this idea in mind that *Czochralski* presented in 1918 a new *method for measurement of the crystallization velocity of metals* where he actually pulled fibers of low melting point metals from their melts [13.6]. Soon after this, *Gomperz* [13.7] used floating dies to control the fiber diameter [an early Stepanov or edge-defined film-fed growth (EFG) process] [13.5].

In the 1950s, single-crystal fiber attracted the attention of researchers due to its high crystalline perfection and outstanding mechanical properties. Those fibers were produced mainly by vapor-phase reactions [13.8]. Research into fiber pulling from the melt, especially for nonconducting materials, remained somewhat latent for approximately 20 years until the end of World War II (1945), the transistor revolution (1947), and the creation of the laser (1960). The works of *Labelle* and *Malvsky* [13.9,10] on the pulling of sapphire fibers from the melt opened a new perspective in fiber research.

Fig. 13.1 Publication dynamics of laser-heated fiber pulling research

In their work of 1971 they grew sapphire fibers by the now famous die-shapes growth method known as edge-defined film-fed growth (EFG) [13.8]. Due to its outstanding mechanical strength, these sapphire fibers were considered good candidates to be used as structural composites.

It was only in 1972 that fiber pulling from the melt received a major contribution. Due to the interest of industry in creating a technique for producing fibers with small diameter, high mechanical strength, and high purity, the floating zone technique was considered. It was *Haggerty* [13.11] who developed the method of four focused laser beams to create a laser-heated floating zone for fiber production. However, this was not the first time that lasers had been used in the growth of bulk samples, as demonstrated by the work of *Cockayne* and *Gasson* [13.12]. Haggerty grew fibers of Al_2O_3 , Y_2O_3 , TiC , and TiB_2 and investigated their mechanical properties. He concluded that, even without optimization of the growth process, the room-temperature strength of $\text{Cr}:\text{Al}_2\text{O}_3$ fibers could reach $9.65 \times 10^9 \text{ N/m}^2$, which had previously been observed only with small, *whisker* single crystals.

In the late 1970s, the development in fiber-optic communication and the need for miniaturization of optical devices, such as miniature solid-state lasers, provided a major impulse for the laser-heated fiber growth technique. During this period, we can highlight the works of *Burrus*, *Stone*, and *Coldren* on the production

of high melting point oxide fibers (Nd:YAG, Nd:Y₂O₃, and Al₂O₃:Cr) and also the room-temperature operation of miniature lasers using Nd:YAG and Nd:Y₂O₃ fibers grown by the two focused laser beam heated pedestal growth method [13.13–15].

Until 1980, the laser-heated technique applied to crystal growth used only two or four laser beams focused over the source material. This condition usually leads to the creation of large radial thermal gradients in the molten zone that could be deleterious for growing crystal [13.8]. The main contribution on the subject of radial thermal flow in the laser-heated crystal growth technique was made by *Fejer* and *Feigelson* [13.16, 17]. They incorporated into the focusing system a special optical component known as a *refluxicon* [13.18], consisting of an inner cone surrounded by a larger coaxial cone section, both with a reflective surface, which converts the cylindrical laser beam into a larger-diameter hollow cylinder surface. This optical component allowed the energy to be distributed radially over the molten zone, reducing the radial thermal gradients [13.19]. This new version of the laser floating zone technique became known as laser-heated pedestal growth, or simply **LHPG**.

In the setup based on the Stanford version of the **LHPG** technique, a CO₂ laser (continuous wave (CW), $\lambda = 10.6 \mu\text{m}$) or Nd:YAG laser (CW, $\lambda = 1.06 \mu\text{m}$) can be used with the laser cavity cooled by water or air flow, depending on the nominal laser power. It is quite common to use a He–Ne laser, propagating parallel to CO₂ laser beam, to act as a guide for the eye in the opti-

cal alignment. The laser beams are guided into a closed chamber through a ZnSe window and hit the refluxicon [13.18], where they are converted as mentioned above into a cylindrical shell and guided to a spherical or parabolic mirror, and focused over the source material as shown in Fig. 13.2. The focusing mirror has a hole in its center to allow the seed holder to be placed in its optical axis and also to avoid vapor material deposition onto the optical mirrors during fiber pulling. The use of a growth chamber allows for a controlled growth atmosphere (special gases or vacuum). There are normally two windows in the growth chamber for visualization of the growth process: it is possible to see the molten zone by using magnifying lenses and with a video system mounted 90° off-axis from the first one. This video system has a microscope attached to it, allowing the viewing of the molten zone and the growing fiber (Fig. 13.3).

Since the implantation of the **LHPG** system at Stanford University laboratories, several modifications have been proposed to improve it. Table 13.1 lists some of these modifications in the **LHPG** technique over the last decades. The first modification to the **LHPG** system was made by *Fejer* himself (1985) when he implemented high-speed diameter control of the fiber during the pulling process [13.20]. Diameter control proved to be essential to obtain high-quality single-crystal fibers and also to improve the efficiency of resulting fiber-optical devices (such as waveguides and solid-state lasers) by decreasing the light scattering at the surface of the fiber.

Due to the fact that the **LHPG** technique has very localized heating, it generates a very large thermal gradient at the growth interface (on the order of

10^3 – 10^4 °C/cm). Uda and Tiller [13.21] used a Pt–Rh(10%) resistive afterheater in order to control the axial thermal gradient at the solid–liquid growth interface [13.21] (Fig. 13.4a). They showed that Cr^{3+} doping concentration in LiNbO_3 single-crystal fiber is affected by an electric field generated at the growing interface, which is proportional to the axial temperature gradient. They could also calculate the diffusion coefficient for Cr in the liquid phase ($3.8 \times 10^{-6} \text{ cm}^2/\text{s}$). Sugiyama et al., in 1993 [13.22], proposed the use of an optical afterheater in order to create a more homogeneous temperature distribution around the growing fiber, to allow the pulling of larger-diameter (0.5–1.0 mm) high-quality *a*-axis strontium barium niobate (**SBN**) fibers for holographic applications (Fig. 13.4b). Larger-diameter fibers presented optical inhomogeneity resulting from internal stress induced during solidification and from anisotropic growth kinetics in the radial direction. Sugiyama et al. reported the improvement in the fiber morphology and also in the fiber composition homogeneity with the use of the afterheater. In the Fejer version of the **LHPG** technique, the arrangement results in very tight focusing on the shoulder of the molten

zone. Phomsakha et al. proposed the use of a Gaussian reflector [13.23] to substitute the refluxicon (Fig. 13.4c). In this way, they achieved a condition for sapphire fiber pulling where not only is the laser radiation spread more evenly over the molten zone but it also impinges on a short length of the newly grown fiber. In this configuration the fiber-pulling limit for high-quality sapphire fibers was extended from 2–3 mm/min to as high as 20 mm/min using He atmosphere. The authors believe that the appropriate distribution of the laser beam in the vicinity of the molten zone is important in minimizing the magnitude of convection currents, which could improve the sapphire fiber quality and allow greater pulling speed.

In 1995 Yokoo et al. modified the **LHPG** system in order to grow low melting point organic compounds [13.24]. The **LHPG** system in its original configuration cannot be applied directly to grow organic single fibers due to their very low melting point and poor thermal conductivity. Even though sublimation occurs more easily due to direct and localized heating by the laser in those compounds, this does not allow for stabilization of the molten zone. The new configura-

Fig. 13.4a–d Modifications to the LHPG system over the years to control/modify the temperature gradient at the solid–liquid interface. tion is based on the insertion of a glass tube to stop the laser beam before it reaches the material to be melted, and the introduction of a gas flow. The authors called this new method indirect laser-heated pedestal growth (ILHPG). The source rod and seed crystal are inserted

into the glass tube from opposite sides of the tube. The CO₂ laser beam is focused onto the glass tube circularly with an axially symmetric irradiance pattern. The laser beam is absorbed by the glass and retransmitted by black-body radiation emission from its inner surface.

As a result, direct and localized heating of the source rod is avoided. With this configuration they were able to produce single-crystal fibers of 2-adamantylamino-5-nitropyridine (AANP). The authors were able to produce AANP crystal fibers with lengths of more than 20 mm and diameters ranging from 300 μm to 2 mm. In addition, it has been experimentally confirmed that the efficiency of second-harmonic generation (SHG) for rod-like AANP crystal grown by the LHPG method is higher than that for conventional AANP crystal grown by Bridgman–Stockbarger method.

While many researchers were making efforts to decrease or homogenize the axial and radial temperature gradient at the solid–liquid interface, respectively, Imai and coworkers (1995), for the growth of potassium niobium tantalate (KTN) fibers, went in the opposite direction [13.25], observing that the thermal axial gradient was not high enough to prevent constitutional supercooling. The authors constructed a gas blower whose nozzle encircled the fiber symmetrically. The flow surrounds the fiber, the molten zone, and the pedestal-like tube. With this modification the authors were able to pull KTN fiber of 400 μm at pulling rates up to 0.4 mm/min, 50 times faster than the conventional top seed solution growth method, suppressing the constitutional supercooling phenomenon. However the fibers still had cracks and showed striations, located mainly at the center.

Brueck et al., in 1996, used an ultrahigh-vacuum (UHV) modified LHPG to grow metal fibers, returning, in a way, to the birth of fiber research [13.26]. They grew UPt_3 and UNi_2Al_3 in order to study their electric property, which is strongly affected by impurities and oxidation. The fibers were about 600 μm in diameter and showed superconductivity behavior down to 400 and 600 mK for UPt_3 and UNi_2Al_3 , respectively. UNi_2Al_3 fiber presented a higher temperature transition when compared with Czochralski single crystals (300 mK) due to the higher crystal quality.

In 1997 Nubling and Harrington introduced a new version of the reflexicon [13.28]. The inner cone was made from a ZnSe window with an Ag-coated diamond-turned cone in the center. By using a window and reflecting cone, they eliminated the need for supporting spokes for the cone and thus the laser beam was not obscured. The entire optical system could produce a calculated spot size as small as 22 μm . For larger-diameter fiber they were able to adjust the spacing between the reflexicon elements so that it was possible to create a larger focused spot that led to more stable growth. In the same year, Brenier et al. devel-

oped a method for producing periodic poling lithium niobate (PPLN) [13.27] single-crystal fiber. They added two identical tungsten electrodes, 250 or 750 μm in diameter, parallel to the growth direction (a -axis) and 6 mm apart, near the growth interface. They applied a 200 V periodic alternating voltage signal and created an electric field parallel and antiparallel to the c -axis. With this configuration they were able to produce periodic alternating ferroelectric domains separated by 1.68 μm with a typical period of 204 ms for the electric field and a pulling speed of 120 mm/h. In 1999 Ardila et al. developed a system to grow single-crystal fiber in a high isostatic pressure environment [13.29]. The authors have shown that fiber growth of $\text{LiNbO}_3\text{:Er}$ and $\text{Ca}_3\text{V}_2\text{O}_8\text{:Er}$ are favored by a high O_2 isostatic pressure during the pulling process. In the case of $\text{Ca}_3\text{V}_2\text{O}_8$ fiber the best results were obtained by a 10 bar O_2 pressure.

Two years later, Ardila et al. proposed another modification to the LHPG technique [13.30]. This time they introduced a bifocal spherical mirror to focus the CO_2 laser. With this modification to the optical system, they managed to create an optical afterheater with the same laser beam as used to melt the compound. They were able to grow c -axis LiNbO_3 with 2 mm diameter without cracks, doubling the diameter obtained with the previous focusing mirror. In the same year, Laversenne et al. [13.31] developed a process to produce concentration-gradient crystals. They describe a methodology to produce pedestals with two different composition (or concentration) regions. During the growth process the liquid phase continuously changes its composition, thus allowing crystallization at the beginning with one composition and finishing with another. This means that, in the same experiment, one may create a *spectroscopic library* (with different doping concentrations) for the determination of the optimum desired properties.

Andreeta et al. proposed in 2002 a modification to the alignment of the LHPG system that allowed the creation of an optical aberration at the focusing point of the CO_2 laser beam [13.32]. In this way it was possible to decrease the axial gradient while maintaining the annular radial distribution in the fiber growth. The authors have shown that the introduction of a 1° deviation from the original parallel laser beam entering the reflexicon could expand the width of the laser beam focused at the molten zone by a factor of 10 (Fig. 13.4d). This leads to a reduction of about 1000 $^\circ\text{C}/\text{cm}$ in the axial temperature gradient at the growing interface (from 3800 $^\circ\text{C}/\text{cm}$ to 2700 $^\circ\text{C}/\text{cm}$) for the Bi–Sr–Ca–Cu–O (BSCCO)

system used as a model material. The following year *Andreeta et al.* published an article describing another approach for automatic diameter control in the **LHPG** technique [13.33]. In this new approach an optical image of the molten zone is digitized and its height and the fiber diameter are monitored by a microcomputer, in an attempt to effectively control the shape of the molten zone and not only the fiber diameter itself.

In 2004, *Carrasco et al.*, using a Nd:YAG-LHPG technique, introduced an electric current flow through the crystallization interface in **BSCCO** fiber pulling [13.34]. They showed that the direction of current flux modifies the fiber quality and also that the choice of appropriate current direction and intensity can improve the texture of the **BSCCO** fibers produced.

Finally, in 2005, *Lo et al.* [13.35] developed a method to produce YAG fibers with a clad structure by introducing a previously grown fiber with a diameter of 68 μm into a fused-silica capillary tube with 76 and 320 μm inner and outer diameter, respectively. They then applied the **LHPG** technique again in the tube with

the fiber and pulled in the downward direction. The result was a core (YAG fiber with 25 μm in diameter) and two more layers. The outer layer proved to be of SiO_2 whereas the inner layer was a mixture of YAG and SiO_2 .

The history of fiber research is very rich and, as mentioned earlier, started before many of the traditional crystal growth techniques, such as Czochralski. The introduction of laser heating for the production of fiber-shaped materials expanded the previous physical limitations for new materials development. High melting point materials could be developed with minimal material lost. Due to its versatility and to achieve the fiber quality needed for some applications, almost once a year a new version/modification appears in the literature for the **LHPG** technique. Some of the changes and proposals for modification to the **LHPG** system described earlier are restricted to the developers' laboratory, mainly due to difficulties in their implementation. However, all of them slightly extended the potential of the **LHPG** technique to create new features for the development of new materials and also to improve the quality of known materials.

13.2 The Laser-Heated Pedestal Growth Technique

The **LHPG** technique, as described in Sect. 13.1, is basically a miniature floating-zone-like method where the heating element is substituted by a focused laser ring to generate the molten zone. The pulling process starts with basically four steps inside the growth chamber, as illustrated in Fig. 13.5. The first step is to align the seed and the pedestal mechanically, both centralized in the optical axis of the laser beam. The next step is to create a small molten zone on top of the pedestal, by turning on the laser and slowly increasing the laser power. In the following step the seed is introduced into the liquid and a molten zone is formed. Finally, the motors start the fiber pulling and rotation, as indicated in step IV of Fig. 13.5. In the following sections the experimental aspects of this technique are presented in terms of source and

Fig. 13.5 Schematic drawing of the four steps performed in the **LHPG** technique: (I) mechanical alignment of the seed and the pedestal and (II) creation of a small molten zone on the top of the pedestal. (III) The seed is then introduced in the liquid phase and there is creation of a molten zone. (IV) The motors are started and the fiber-pulling process begins ►

seed preparation and automatic diameter control (ADC) systems.

13.2.1 Source Preparation and Seeding

The source material (pedestals) used to grow single-crystal fibers can be prepared by cutting a previous bulk-grown crystal or dense ceramic or by the cold extrusion process. Pedestals obtained from bulk crystals or dense ceramics usually have a square section, which is not the best geometry to fit the cylindrical focusing laser beam. In this way one more step is needed before the fiber growth process, if one wants to avoid the corners of the square section pedestal going inside the liquid phase during the pulling process, destabilizing the contact angle. To avoid this effect it is necessary to round the pedestal.

In the cold extrusion process, an organic binder (such as polyvinyl alcohol) is added to the material of reacted or unreacted powder until it achieves a plastic-like consistency, and then it is forced, with a manual press, through a 5 mm long 1 mm diameter stainless-steel cylindrical tube [13.36]. This source material does not need to be cut, as it already has a convenient geometric shape. The pedestals are then allowed to dry at ambient temperature for at least 3 h, and can then be used as a source for crystal growth. This method for producing source materials has many advantages over conventional approaches, such as the small amount of materials needed and the possibility of producing source rods from reagents (green-rods), which also enables better stoichiometric control. When green rods are used in the LHPG system, the three steps in material

preparation are reduced to just one (synthesis, sintering, and crystal growth). In previous works, we have shown that the fiber quality of high melting point materials is related to the pedestal heat treatment previous to the growth process [13.37, 38]. The longer the pedestal heat treatment prior to the growth process, the darker the resulting fiber. The origin of the dark color of the fiber may be related to the creation of oxygen vacancies when the pedestal is processed at high temperatures, since changes in the stoichiometry were within experimental error. Crystals grown from an unreacted source (cold extrusion process) are colorless and show good transparency, as shown in Fig. 13.6.

Another feature of the LHPG technique is the possibility to prepare pedestals with compositional variation, such as in the method developed by *Laversenne et al.* [13.31] to create a different doping concentration along the fiber axis. This method was also used by *Barbosa et al.* [13.39] by conveniently joining two cold-extruded sections of CaMoO_4 and SrMoO_4 . The obtained fiber was pure CaMoO_4 at one end and pure SrMoO_4 at the other, both single crystals, with a continuous lattice parameter variation between the two pure sections (a gradient crystal fiber). This kind of crystal can be useful for x-ray optics applications.

The seeds used in the LHPG system must have the same characteristics as for any other crystal growth technique. However, since LHPG is a very powerful tool for new materials development, it is usual to use wires (Pt, Au, etc.) or small pieces of the pedestal (polycrystalline material) as a startup seed for the pulling process due to the impossibility of obtaining previous oriented crystals by any other growth technique. As would be expected, it has been shown that the seed plays a major role in the quality of the grown fiber. *Lu et al.* [13.40] studied seeding effects in the Bi–Sr–Ca–Cu–O system. They used Pt and Au wires to start the pulling process. The use of wires of Pt creates a very high thermal gradient at the wire–melt interface, thus nucleating grains that are aligned with the preferential growth direction perpendicular to the wire surface. While most of the grains grow out of the fiber, some of them grow parallel to the fiber axis and later dominate the grain structure. Grain selection usually takes place in the first 1–4 mm of the grown fiber, and depends on the diameter. For the same materials Au wires did not show the same results. The difference between Pt and Au wire seeding, according to the authors, is due to the reduced wettability or higher thermal conductivity of Au. Due to the considerably larger thermal conductivity of gold wires, the laser power (melt temperature)

Fig. 13.6a,b Single-crystal LaAlO_3 fibers produced from different types of pedestals: (a) LaAlO_3 fiber grown from prereacted pedestal, and (b) LaAlO_3 fiber grown from unreacted pedestal (green-rod)

had to be increased significantly to cause the melt to adhere to the gold wire, and then decreased abruptly to create a normal-sized molten zone. In this way, higher-temperature phases dominate the beginning of the pulling process ($\text{CaO} + \text{liquid}$ and $\text{CaSrCu}_2\text{O}_4 + \text{liquid}$). *Chen* and coworkers [13.41] have shown that it is possible to pull stoichiometric LiNbO_3 single-crystal fibers from pedestals with 50 mol % Li_2O , if a seed with 58 mol % Li_2O is used. Using this strategy, in the beginning of the growth process an excess of Li_2O is inserted into the molten zone due to a small fraction of the seed that melts. In this way, since the early stages of the growth process, the crystal is allowed to solidify to 50 mol % Li_2O . In other words, when the solidified crystal composition reaches 50 mol % Li_2O , the fiber will have the same composition as the pedestal (source).

Another interesting work was performed by *Ishibashi* et al. [13.42], who studied facet suppression in the growth of $\text{YAG}:\text{Ca}:\text{Cr}$ fiber by the LHPG technique. This is a major issue for optimization of solid-state laser efficiency and holographic recording. In order to improve the laser operation efficiency, the authors studied the best crystallographic seed orientation in the growth of $\text{YAG}:\text{Ca}:\text{Cr}$ fibers. They found that facet suppression occurs for a crystallographic oriented seed at 15° from $\langle 100 \rangle$ to $\langle 110 \rangle$. For SBN single-crystal fibers, *Sugiyama* et al. [13.22] reported that the only way to obtain ridge fiber (facet suppression) is to use a ridge-fiber crystal as a seed.

13.2.2 Automatic Diameter Control Applied to LHPG

Despite the precautions intended to ensure stable growth conditions, as will be described in the following sections, it is found that excessive variations in the fiber diameter occur during open-loop growth. It is thus necessary to design closed-loop systems to regulate fiber diameter during the growth process. These systems contain basically two major components: a real-time dimension measurement apparatus and a proportional controller feeding back to the laser and/or motor speed ratio. Two main approaches have been developed to control the fiber diameter in the LHPG system. The first is based on quasisinusoidal interference fringes as the measurement technique observed in the far field of a fiber side-illuminated by a beam of coherent light [13.20]. The second method is based on artificial vision of the molten zone of the growing fiber [13.33].

The theoretical diameter variation resolution $(\Delta\phi/\phi)_{\min}$ of the system based on the interference

fringes can be obtained from a ray-tracing analysis, as shown in (13.1)

$$\left(\frac{\Delta\phi}{\phi}\right)_{\min} = \left(\frac{s}{f}\right)g(n, \theta), \quad (13.1)$$

where s is the distance between two adjacent elements in a photodiode array, f is the focal length of the lens that projects the interference pattern onto the photodiode array, and $g(n, \theta)$ is a geometrical factor dependent on the refraction index of the fiber n and the angle between the laser beam and the detector θ . This factor is obtained from ray-tracing analysis and is typically between 0.4 and 1.0. The quantity s/f can be described as the angular resolution of the optical system. The monotonic improvement in the resolution with increasing focal length predicted by (13.1) is eventually limited by signal-to-noise considerations. *Feyer* et al. [13.20] have shown that this ADC system allows the production of fibers with diameter fluctuations as small as 0.02%.

Another way to introduce an automatic diameter control system is to use the measurements of a charge-coupled device (CCD) camera image of the growing fiber as a feedback for the CO_2 laser and the fiber-pulling motor [13.33]. The video hardware captures the image, which is recorded and processed by a personal computer (PC) in gray scale mode. The black-body radiation from the molten zone and the high temperature gradient at the melting (pedestal) and crystallization (fiber) interfaces (10^3 – 10^4 °C/cm) make it easy to identify those interfaces positions, due to the good contrast in the image at those points in the LHPG technique. The software uses those positions to measure the fiber diameter and the height of the molten zone. In this way, two predefined areas in the image are measured. The first area is a vertical rectangle (3×354 pixels) and the

Fig. 13.7 Measurements on a captured image of a growing LaAlO_3 fiber (after [13.33])

other one is a horizontal rectangle (354×3 pixels), as shown in Fig. 13.7. The software recognizes the value of all the pixels (from 0 to 255) inside these areas. The next step is to count the number of white pixels inside the predefined area (molten material). The number of these pixels is proportional to the height of the molten zone (vertical) and to the fiber diameter (horizontal). Based on the vertical pixel count, the software recognizes the position of the crystallization interface, using this information to take the horizontal measurement just a few pixels below the crystallization interface (because of the better contrast on the molten zone). After selecting the desired diameter and molten zone height, the software modifies the laser power and pulling rate to match the number of pixels established by the crystal grower (the set point). One advantage of this system is that it is independent of the material used (opaque or transparent). Diameter control of better than 2% was obtained for growth of LaAlO_3 single-crystal fibers, using unreacted pedestals with an appropriate mixture of La_2O_3 – Al_2O_3 , with diameter fluctuation intentionally introduced in the pedestal up to 20% (Fig. 13.8). It has been shown that this ADC system can reduce the overall fiber diameter to less than 1% for dense pedestals, with regions on the order of 1 cm with near-zero variations.

13.3 Fundamentals

Many of the unique features of the LHPG technique are consequences of the very small liquid-phase volume necessary to grow crystals and in the following sections we shall discuss both experimental and theoretical aspects of the pulling process.

13.3.1 Conservation of Mass

It is possible to correlate the pedestal and fiber cross-section areas with their respective pulling rates if we consider that all molten materials from the pedestal are crystallized as a single-crystal fiber. If we are allowed to consider that the pedestal used has the same density of the growing crystal fiber, we can further simplify this relation as shown in (13.2)

$$\begin{aligned} \rho_{\text{fib}} r_{\text{fib}}^2 v_{\text{fib}} &= \rho_{\text{ped}} r_{\text{ped}}^2 v_{\text{ped}} \\ \text{if: } \rho_{\text{fib}} &= \rho_{\text{ped}} \quad r_{\text{fib}} = r_{\text{ped}} \sqrt{\frac{v_{\text{ped}}}{v_{\text{fib}}}}, \end{aligned} \quad (13.2)$$

Fig. 13.8a,b A fiber pulled from a pedestal prepared with diameter fluctuations of up to 20%. (a) Unreacted pedestal (green rod) with the introduced diameter variation and (b) fiber pulled from the same pedestal showing that the diameter fluctuation was corrected by the automatic diameter control system (ADC)

Both systems have their advantages and limitations. The interference system showed better resolution results, however it is dependent on the fiber transparency, which affects the resolution of the apparatus: $g(n, \theta) = g(\theta) \approx 1/\theta$. On the other hand, the artificial vision system, although more versatile, is not adequate for low melting point materials ($< 800^\circ\text{C}$) due to their poor black-body emission.

where ρ_{fib} , r_{fib} , v_{fib} , and ρ_{ped} , r_{ped} , v_{ped} are the density, fiber radius, and pulling rates of the fiber and pedestal, respectively.

In laser-heated pedestal growth, the laser power and pulling rates are parameters that we can modify during the crystal growth process. It is evident that the crystal diameter will be constant if all the physical parameters remain unchanged. However, it is reasonable to assume that small imperfections in the pedestals may occur. In this way, if some variation of the source cross-sections remains, it is necessary to change one of the growth parameters in order to keep the fiber diameter constant. The simplest solution is to modify the pulling rate, assuming that the pedestal upward pulling rate remains unchanged.

That is why a fast and effective diameter control system is important, allowing for only very small changes in the pulling rate to correct for possible nonuniformity of the geometry of the pedestals used.

13.3.2 Balance of Heat Transfer

A schematic representation of the most important heat fluxes during fiber pulling is illustrated in Fig. 13.9. The energy delivered by the CO₂ laser that is used to keep the molten zone height is: conducted through the fiber and pedestal, lost to the growth chamber by irradiation, due to the black-body emission, and convection to the fluid inside, when present. There is also the latent heat of solidification and melting generated at the fiber-liquid and pedestal-melt interfaces.

In the LHPG system it is reasonable to assume heat transfer in one dimension, considering the heat fluxes in a semi-infinite cylinder, moving with velocity v in the z -direction [13.43]. The equation for the heat transfer can be written as

$$\frac{d^2 Y}{dZ^2} - 2(\text{Bi}_{\text{total}})Y - 2\text{Pe} \frac{dY}{dZ} = 2\text{Pe} \frac{dY}{d\tau}, \quad (13.3)$$

where $Y = (T - T_0)/(T_i - T_0)$, $Z = z/a$, and $\tau = v_{\text{fib}}t/a$; T_0 is the ambient temperature in the surroundings of the growing fiber, T_i is the growing temperature interface, a is the fiber radius, $\text{Bi} = ha$ is the total Biot number, h is the effective cooling constant (convective and radiative), and Pe is the Péclet number defined as $\rho c_p v_{\text{fib}} a / 2K$, where ρ is the solid density, c_p is the thermal capacity, and K is the solid thermal conductivity. From the solution of this equation it is possible to obtain an analytical solution for the thermal gradient at the crystal-liquid interface ($G_{s,i}$) as shown

in (13.4)

$$G_{s,i} = \left(\frac{dT}{dz} \right)_{z=0} = -(T_i - T_0) \left\{ \left[\text{Pe}^2 + 2(\text{Bi}) \right]^{\frac{1}{2}} - \text{Pe} \right\} \left(\frac{1}{a} \right). \quad (13.4)$$

The laser-heated pedestal growth method produces steeper thermal gradients at the growing interface than any other crystal growth method (ranging from 10^3 – 10^4 °C/cm). This high temperature gradient at the growing interface is responsible for the high pulling rate in this technique, allows the pulling rate to be mm/min instead of mm/h as is typical for conventional crystal growth methods. However, these same elevated thermal gradients also have some disadvantages, one of which is that it produces greater thermal stresses which restrict the maximum crystal diameter that can be grown before cracks develop. Brice [13.44] has shown that this maximum diameter can be determined based on the mechanical and thermal properties of the compound (13.5)

$$\left| \frac{dT}{dz} \right|_{\text{max}} \approx \frac{4\varepsilon_b}{\alpha a^{\frac{3}{2}}} \left(\frac{1}{h} \right)^{\frac{1}{2}}, \quad (13.5)$$

where $|dT/dz|_{\text{max}}$ is the absolute value of the maximum allowed thermal gradient at the growth interface, ε_b is the breaking strain, α is the coefficient of linear thermal expansion, a is the radius of the fiber, and h is the cooling constant.

The temperature gradient at the crystallization interface, in a conventional LHPG system, has a strong dependence on the fiber diameter. Andreetta [13.45] used lithium niobate as a material model due to its technological importance, for a study on the effects of the temperature gradients at the solid-liquid interface on the maximum attainable fiber diameter without cracks. For temperature measurements a very small Pt/Pt-Rh thermocouple (60 μm in diameter) attached to the pulling system was used. The thermocouple was inserted into the liquid phase and pulled through the solid-liquid interface. Single-crystal fibers of 40 mm in length and ranging from 300 to 1200 μm in diameter were pulled from single-crystal pedestals, along the c -axis. With this system it was possible to measure the high axial thermal gradient at the solid-liquid interface as a function of fiber radius (Fig. 13.10). From this data and the maximum diameter, above which the fiber cracks (13.5), we determined for lithium niobate a critical radius of 470 μm (Fig. 13.10).

Fig. 13.9 Schematic drawing of the heat fluxes acting during the single-crystal fiber growth process

Fig. 13.10a,b Temperature gradient at the solid–liquid interface during LiNbO₃ single-crystal fiber growth. **(a)** The *continuous* line represents the maximum thermal gradient that the material can handle before it cracks (13.5) and the *dashed* line is the fitting of the temperature gradient measurements based on (13.4). $R_c = 470 \mu\text{m}$ is the critical radius above which fiber cracking results during the growth process. **(b)** LiNbO₃ single-crystal fiber with 1 mm diameter, showing cracks produced by generated thermal stress

The high axial temperature gradient at the solid–liquid interface results in a wide number of advantages, including higher growth rates, ferroelectric domain alignment during growth (LiNbO₃), and the possibility of obtaining high-temperature metastable phases of certain compounds. Another important effect of the high axial temperature gradient is to prevent constitutional supercooling. The condition for constitutional supercooling can be written as

$$\frac{G}{v} \leq \frac{mC_s}{D_l} \left(\frac{1-k_0}{k_0} \right), \quad (13.6)$$

where G is the absolute value of the temperature gradient at the solid–liquid interface, v is the pulling rate, m is the absolute value of the liquidus slope, C_s is the concentration in the solid phase, D_l is the diffusion coefficient of the solute in the liquid, and k_0 is the equilibrium distribution coefficient (the ratio between the solid and liquid concentration $-C_s/C_l$). The smaller the fiber radius, the greater the pulling rate allowed before constitutional supercooling occurs. Lu et al. [13.40] systematically studied the influence of constitutional supercooling on the growth of Bi₂Sr₂Ca₁Cu₂O₈ crystal fibers. They found a critical value for the constitutional supercooling ($1.0 \times 10^{12} \text{ K s/m}^2$) below which the pulled fiber became polycrystalline. They also esti-

mated that, for a fiber 30 μm in diameter, the maximum speed allowed should be around 26 mm/h.

Unfortunately, the same axial temperature gradient is also responsible for a high level of stress in the grown fiber. The thermal stresses induced by temperature gradients are the main cause of the formation of various crystallographic defects in the fiber. The expression for approximate calculation of the dislocation density (N_d) in terms of the axial temperature gradient was performed by Prokofiev et al. for the Bi₁₂SiO₂₀ (BSO) compound [13.46], yielding

$$N_d = \frac{\alpha}{b} \frac{dT}{dz} - \frac{2\varepsilon_b}{ba}, \quad (13.7)$$

where b is the Burger's vector and dT/dz is the axial temperature gradient at the crystallization interface. Using the calculated values of the axial temperature gradient, it is possible to evaluate the dislocation density in the fiber. The calculated value of N_d for BSO fibers was $5 \times 10^5 \text{ pits/cm}^2$ for fibers with 1 mm diameter, which is in good agreement with the value estimated by the chemical etching method ($1 \times 10^5 \text{ pits/cm}^2$). Prokofiev et al. also estimated that a BSO fiber with diameter below 100 μm should be free-dislocation.

13.3.3 Mechanical Stability

The shape of the molten zone is a very important growth parameter, especially in a floating-zone-like technique such as LHPG. The variation of the contact angle is responsible for the diameter fluctuation of grown fibers. The stability of a liquid trapped between two cylindrical plates has been studied for more than a century. Interest in this topic starts mainly from the 1950s due to the importance of the new (at that time) technology of semiconductors crystals.

For an analysis of the molten zone shape of the miniature floating zone let us consider an isotropic molten zone with length L , volume V , and surface area S , suspended between two axial solid cylinders of radius r_{fib} and r_{ped} . Kim et al. [13.47] studied the maximum stable zone length for sapphire and silicon crystals. The value found was $L_{\text{max}} = \pi\phi$, where ϕ is the fiber diameter.

If we consider also that the liquid–fiber and liquid–pedestal contact angles are ψ_{fib} and ψ_{ped} , respectively, and that the total energy involved in the liquid is composed of potential gravitational and surface energy, the molten zone will acquire the shape that allows for total

energy minimization as shown in (13.8)

$$E_T = E_g + E_s = \pi \rho g \int_0^L r^2(z) z dz + 2\pi \sigma \int_0^L \left(\sqrt{1 + \left(\frac{dr}{dz} \right)^2} \right) r(z) dz, \quad (13.8)$$

where g is the acceleration due to gravity, ρ is the density of the liquid, and σ is the surface tension. Since the effect of gravity on LHPG is very small, it can be neglected in comparison with the surface energy [13.19]. In this way, the problem is reduced to the minimization of the surface energy. Figure 13.11 illustrates several profiles of molten zones obtained for different fiber-pedestal diameter reductions, based on the numerical solution of the minimization of the surface energy of the liquid phase. *Saitou et al.* [13.48] developed an analytical solution for the liquid-phase profile in the floating zone technique for a pedestal-crystal diameter ratio of 1. They showed that minimization of the surface free energy (13.8) followed by application of the principle of variation led to the dimensionless expression

$$\frac{dx}{dy} = \frac{\frac{y^2}{2} + \lambda y + C_0}{\sqrt{1 - \left(\frac{y^2}{2} + \lambda y + C_0 \right)^2}}. \quad (13.9)$$

Fig. 13.11 Molten zone profile shapes obtained for different fiber-pedestal diameter reductions, obtained by numerical solution of the minimization of the surface energy of the liquid phase (the pedestal radius was normalized to 1) (after [13.19])

Solving (13.9) and returning to the dimensional form we obtain (13.10) [13.49]

$$x(y) = \frac{y^3}{6C^2} + \frac{\lambda y^2}{2C} + C_0 y + C_1 C, \quad (13.10)$$

where λ , C_0 , and C_1 are constants (given in terms of the floating zone height, pedestal diameter, and molten zone surface area), C is the capillary constant (defined as $C = (2\sigma/\rho g)^{1/2}$), σ is the surface tension, ρ is the liquid density, and g is the acceleration due to gravity [13.48].

When minimization of the energy takes place, considering an isotropic system, another way to look at the problem is to realize that equilibrium of the molten zone is reached when there is also balance of the surface tensions at the liquid-solid-gas junction. This junction defines what is called the wetting angle and it is possible to express the contact angle by

$$\cos \varphi_0 = \frac{\sigma_{l,g}^2 + \sigma_{s,g}^2 - \sigma_{s,l}^2}{2\sigma_{l,g}\sigma_{s,g}}, \quad (13.11)$$

where $\sigma_{l,g}$, $\sigma_{s,g}$, and $\sigma_{s,l}$ are the liquid-gas, solid-gas, and solid-liquid surface tensions, respectively.

When the wetting angle reaches this equilibrium value, the growth process is stable and there should be no diameter fluctuations. However in real crystal growth processes we are faced with nonideal situations which cause fluctuations of the floating zone shape, thus modifying the contact angle. Again for the LHPG technique, there is always the need for good diameter control to obtain high-quality fibers.

13.3.4 Growth Under Controlled Atmosphere

The growth atmosphere and the nature of the solid and liquid phases are also factors that influence the molten zone profile. The effects of external pressure on the melt properties and equilibrium of solid and liquid phases began to be studied in the first decades of the 20th century [13.50]. Fiber growth under different atmospheres using laser-heated systems was first explored in the pioneering work of *Haggerty* [13.11]. He grew fibers under air, Ar, Cl₂, H₂, and CH₃ alone or in combination. It was noticed that the mechanical strength of the fiber was dependent on the growth atmosphere used. *Ardila et al.* reported fiber pulling under controlled high external pressure [13.29]. In this work they modified the LHPG technique to grow crystal fibers in a system that could handle up to 15 atm of oxidizing, reducing or inert gas and studied the profile of the liquid phase. They used various materials, such as Ba_{0.77}Ca_{0.23}TiO₃ (BCT), CaMoO₄

(CMO), $\text{Ca}_2\text{FeMoO}_6$ (CFMO), and $\text{Ca}_{1-x}\text{Sr}_x\text{MoO}_3$ (CSMO) with $0 \leq x \leq 1$ [13.49, 51]. The values for the capillary constant and surface tension coefficient for all of these compounds were quite similar.

Phomsakha and coworkers studied the effect of the atmosphere on Al_2O_3 single-crystal fiber pulling [13.23]. They report that the best atmosphere is He gas, but if the pressure is increased to 15–20 Torr the fiber transmission decreases. They found that the optimum pressure was 5 Torr of He. Lower pressure values allow for vaporization that leaves oxygen in the melt, which is the main cause of the formation of microvoids. Other gases, such as N_2 , Ar, and air presented lower transmission measurements. Wu et al. [13.52] grew Ti-doped sapphire fibers under various atmosphere (N_2 , H_2 , Ar) in order to improve the Ti concentration in the fiber. They found that the use of an N_2 atmosphere increased the Ti fiber concentration when compared with experiments performed in air atmosphere, although the fibers presented dark regions on the surface and in the interior. In pure H_2 atmosphere, quite a large amount of white fog-like matter volatilized from the melting zone and was deposited onto the surfaces of the fiber and the furnace wall. The cross section of grown fiber was not circular and the grown fiber was useless [13.52]. However, a mixture of H_2 and Ar gas resulted in fibers without inclusions or bubbles inside. This last mixture allowed the researchers to obtain high-quality laser elements.

13.3.5 Dopant Distribution

As in any crystal growth process, the control of the dopant distribution along the crystalline matrix is desirable for many technological applications such as laser hosts and periodic poled ferroelectric crystals. Sharp et al. developed a model based on mass conservation for fiber pulling [13.53], shown in (13.12)

$$\frac{C_f(z)}{C_{S0}} = k_{\text{eff}} \left[C' e^{-\beta \frac{z}{v}} + \frac{\alpha'}{\beta} \left(1 - e^{-\beta \frac{z}{v}} \right) + \frac{\alpha'(C' - 1)}{(\beta - \gamma)} \left(e^{-\gamma \frac{z}{v}} - e^{-\beta \frac{z}{v}} \right) \right]. \quad (13.12)$$

Assuming that $\alpha' = \pi r_{\text{fib}}^2 v / V$; $\beta = (\alpha' k_{\text{eff}} + 1 / \tau_{\text{ev}})$; $\gamma = (v r_{\text{fib}}^2) / (\eta r_{\text{ped}})$, $C_f(z)$ is the fiber concentration at a point z , C_{S0} is the source concentration, k_{eff} is the effective distribution coefficient, C' is the fractional loss of dopant from the source rod at $z = 0$ due to evaporation, r_{fib} , r_{ped} , v , η , τ_{ev} , and V are the fiber radius, pedestal radius, pulling rate, characteristic length (not usually susceptible to measurement),

the evaporation constant, and the molten zone volume, respectively [13.53]. With this model, Sharp et al. could describe the observed concentration profile for Ti: Al_2O_3 fiber growth. Some CW laser applications at high power levels may require periodically doped crystals, as in the case of periodically poled $\text{LiNbO}_3\text{:Hf}$ and $\text{LiNbO}_3\text{:Nd}^{3+}$ (PPLN) [13.54]. The intrinsic characteristics of the growing process (high pulling rates, unidimensional growth-like process, and small molten volumes) usually led to the growth of homogenous dopant distribution in the crystal fiber.

However it is possible to intentionally change this distribution profile by modifying the growth conditions, such as introducing a sinusoidal temperature fluctuation at the molten zone [13.54]. In this case the dopant concentration can be expressed as a function of growth time, by applying also the mass conservation of the dopant. It is assumed that the dopant is supplied from the incoming pedestal. Dopant loss results from evaporation from the surface of the molten zone and from dopant being taken up by the growing fiber. Thus, the evaporation may be characterized by an evaporation time constant τ_{ev} defined as the time it takes for the concentration of dopant in the melt to decrease by a factor of e^{-1} when the fiber and pedestal are in a stationary state, i.e., at zero growth rate. Hence, the dopant concentration in the melt, considering the oscillation effects, can be expressed by (13.13)

$$\begin{aligned} \frac{dC_m}{dt} = & \frac{\pi r_{\text{ped}}^2 C_s(t) v_{\text{ped}}}{V} - \frac{\pi r_{\text{ped}}^2 k_{\text{eff}} C_m \frac{dF_p(t)}{dt}}{V} \\ & - \left[\frac{\pi r_{\text{fib}}^2 k_{\text{eff}} C_m v_{\text{fib}}}{V} + \left(\frac{\pi r_{\text{fib}}^2 k_{\text{eff}} C_m \frac{dF_f(t)}{dt}}{V} \right) \right] \\ & - \left(\frac{C_m}{V} \frac{dV}{dt} \right) - \frac{1}{\tau_{\text{ev}}} C_m, \end{aligned} \quad (13.13)$$

where C_m is the melt concentration, $C_s(t)$ is the initial pedestal concentration due to the instabilities at the startup of the melting process [13.54], r_{fib} and r_{ped} are the fiber and pedestal radii, respectively, $k_{\text{eff}} = C_f / C_m$ is the effective distribution coefficient, C_f is the fiber concentration, v_{ped} and v_{fib} are the pedestal and fiber pulling rates, respectively, V is the molten zone volume that was approximated to a conical section. $F_p(t)$ and $F_f(t)$ are functions for the periodical input oscillations, which were $A_p \sin(\omega t)$ and $A_f \sin(\omega t)$ for the pedestal melting and fiber growth, respectively [13.54]. The total molten zone oscillation amplitude is $A_p + A_f$.

Equation (13.13) can be numerically solved. The experimental input data required for the program were oscillation amplitude, r_{fib} , r_{ped} , k_{eff} , v_{ped} , v_{fib} , and fre-

Fig. 13.12 Axial concentration profile measurement (dashed lines) for a frequency of 16 mHz molten zone oscillations, and corresponding simulation (continuous line) (after [13.33])

quency. The evaporation time constant τ_{ev} was used to minimize the difference between the calculated and measured Cr^{3+} concentration profile. The typical τ_{ev} values lay within a range of 3–4 min for several experiments, similarly to the $Al_2O_3:Ti$ fiber growth performed by Sharp et al. [13.53] without periodic oscillations. A good match between the measured and the calculated concentration profile with an oscillating molten zone can be verified when they are plotted together, as shown in Fig. 13.12. This means that the growth interface position corresponded directly with the periodic input program. With this new approach to single-crystal fiber growth, it is possible to predict and set the distance between two dopant concentration maxima. Also it is possible to pull fibers with alternating uniform and periodic concentration doping profiles regions.

Up to now it has been considered that the pulling of the fibers is unidimensional. Although for the thermal and composition axial profile this is a good approximation, the radial distribution must be considered to explain some of the observed growth aspects. Liu et al. recently observed that $Al_2O_3:Mg$ fibers present defects at their centers [13.55]. The radial Mg concentration showed that the center of the fiber is richer in Mg atoms. They proposed that this high concentration is due to Marangoni convection that creates a flow from the surface towards the center. This thermocapillary convection causes the flow to drift from the hot side (near the center, at the external part of the floating zone) to the cold side (at the solid–melt interface) along the melt–gas interface and then back from the cold side to the hot side near the axial center. This is highlighted as the main cause of excess dopant at the fiber center. Constitutional supercooling is then the responsible for the

Fig. 13.13a,b Two possible configurations for the convection pattern inside the molten zone in a fiber-pulling process: (a) Laser radiation absorption in the opaque melt occurs at the liquid surface, leading to Marangoni convection, and (b) semitransparent melt, leading to the creation of a hot spot inside the molten zone at the focus point, generating flow competition with the Marangoni convection

creation of fiber defects at the center. Figure 13.13 illustrates two possible configurations for the fluid flow in the molten zone during fiber pulling. Figure 13.13a represents a molten zone opaque to the laser source, and thus all energy is absorbed in the liquid surface, creating a flow as Liu et al. described [13.55]. Figure 13.13b illustrates the condition for a material that is semitransparent to the applied laser source. In this condition a hot spot may be formed in the liquid center, creating competition between the two liquid flows. Erdei et al. [13.56] suggested that the configuration shown in Fig. 13.13b may be the cause of the radial segregation of Ba in the SBN fiber growth process. In the same work, the authors suggested that the radial dependence of the effective distribution coefficient can be expressed by

$$k_{\text{eff}}(r) = \frac{k_0}{k_0 + (1 - k_0)e^{-v\frac{\delta(r)}{D}}}, \quad (13.14)$$

where $k_{\text{eff}}(r)$ is the radial effective distribution coefficient, k_0 is the equilibrium distribution coefficient, v is the pulling speed, D is the diffusion coefficient of the element in the liquid phase, and $\delta(r)$ is the radial thickness distribution of the diffusion layer that forms ahead of the solidification interface during stationary growth.

13.3.6 Pulling Crystalline Fibers Under Electric Field

During crystallization of ionic melts, Uda et al. [13.21] have shown that an electric field will be present in both the liquid and solid, arising for at least two rea-

sons: differential partitioning of opposite-valence ions to place a net charge of one sign on the liquid boundary layer (crystallization electromotive force, EMF) and a Seebeck coefficient produced by the temperature dependence of the equilibrium ion concentration. The thermoelectric potential difference $\Delta\varphi$ between a location at temperature T_1 in the solid and a location at temperature T_2 in the liquid is given by [13.21]

$$\Delta\varphi = \alpha_s(T_1 - T_i) + \alpha_l(T_i - T_2) + \alpha_i v, \quad (13.15)$$

where v is the pulling rate, T_i is the interface temperature, α_i is the crystallization EMF coefficient, and α_s and α_l are the thermoelectric coefficients for the solid and liquid, respectively. The electric field generated at the interface during fiber pulling of some ferroelectric compounds is sufficient to orient the ferroelectric domains in situ, as in the case of LiNbO_3 [13.19].

Tiller et al. [13.58] investigated the effect of a strong interface field during the growth of TiO_2 -based crystals pulled by LHPG technique. According to the authors, when the field-driven flux is appreciably greater than the interface partitioning flux, a stationary-state solute

profile in the solid of an anomalous nature can be maintained. A steady-state solute profile requires the following to hold [13.58]

$$\left(\frac{D_s C_s}{kT}\right) q_s E_s \gg V k_0 C_l^i, \quad (13.16)$$

where D_s , C_s , q_s , and E_s are the diffusion coefficient, solute concentration, effective solute charge, and electric field, respectively, while k_0 is the solute distribution coefficient and C_l^i is the concentration in the liquid phase at the growth interface.

Using the electrical-assisted laser floating zone technique (EALFZ), Carrasco et al. studied the effect of a direct electrical current applied through the solidification interface for superconducting oxide materials [13.34]. In the EALFZ process the fiber can be grown with a direct current (DC) by connecting the positive and negative poles, respectively, to the seed and feed rod samples, or by a reverse current (RC) if the negative and positive poles are connected to the seed and feed rod samples, respectively. The application of a DC current during the EALFZ process can

Fig. 13.14a–l Scanning micrograph of longitudinal sections of BSCCO fiber grown at $R = 15$ mm/h without current (NC fiber) (a,d,g,j) with direct current (DC fiber), (b,e,h,k) and with reverse current (RC fiber) (c,f,i,l). Region I – seeding initial transient. Region II – fiber steady-state region. Region III – frozen melt. Region IV – melting interface. The dotted line corresponds to the seed–fiber interface (after [13.57])

drive the system towards equilibrium, since it drastically changes the solidification features, namely the solute ion distribution, phase equilibrium, and crystal growth kinetics [13.57] (Fig. 13.14). Accordingly, important changes in phase structure, crystal morphology, and grain alignment are observed. The presence of the electric field through the solid–liquid interface accelerates the solute ions until a drift velocity R' ($R' = \mu E$) is reached. In this way, the original Burton–Prim–Slichter (BPS) theory equation for the effective distribution coefficient is modified to [13.34, 59]

$$k_{\text{eff}} = \frac{1 + \frac{R'}{R}}{1 + \left[\frac{1}{k_0} \left(1 + \frac{R'}{R} \right) - 1 \right] \exp \left[\left(-\frac{R\delta}{D} \right) \left(1 + \frac{R'}{R} \right) \right]}, \quad (13.17)$$

where R is the interface velocity, k_0 is the equilibrium distribution coefficient, D is the diffusion coefficient of the element in the liquid phase, and δ is the thickness of the diffusion layer that forms ahead of the solidification interface during stationary growth. Thus, the effective distribution coefficient k_{eff} is a set of two competition processes:

1. The rejection/acceptation of the solute for $k_0 < 1$ and $k_0 > 1$, respectively, by the solid–liquid interface
2. The mobility difference of the solute and solvent ions under the applied electric field in the diffusion layer.

When ions move towards the solid–liquid interface due to the application of a direct current (R' positive) the electrical field will increase k_{eff} . On the contrary, a decrease in k_{eff} is observed for the condition of R' negative, when the ions move away from the interface. It is important to point out that, in the presence of an electrical field and for a given value of interface velocity R ,

the effective distribution coefficient can exhibit values over a wide range, even outside of the normal range situated between k_0 and unity [13.34]. Useful examples of the effect of the electric current on k_{eff} were given by Pfann [13.60]:

1. The refinement of an ingot from an element for which k_0 is close to unity, by increasing the absolute value of $(1 - k_{\text{eff}})$
2. Segregation hindrance by making k_{eff} close to unity
3. Simultaneous zone refining even when solutes have k_0 values lying on opposite sides of the unity, forcing them to move to the same side of an ingot.

An external alternating electric field can also be applied to a LHPG fiber during the pulling process without physical contact with the growing fiber. This is performed in order to produce periodic inversion of ferroelectric domains, such as in the method developed by Brenier et al. described in Sect. 13.1. Lee et al. showed that assuming a uniform electric field E in the fiber cross-section, the accumulated E field, $E_{\text{acc}}(\bar{z})$ that the grown fiber experiences at position \bar{z} during the poling process can be expressed by the convolution integral [13.61]

$$E_{\text{acc}}(\bar{z}) = E_0 \int_{-\infty}^{+\infty} \text{rect} \left(\frac{(\bar{z} - z)}{W_e} - \frac{1}{2} \right) \sin \left(\frac{2\pi f z}{v} \right) dz, \quad (13.18)$$

where E_0 is the electric field at start point in the center of the poling region, W_e is the effective poling length, f is the applied electric field frequency, rect is the rectangular function (also known as the rectangle function, rect function, unit pulse, or the normalized boxcar function) [13.61], and v is the pulling rate. With this process, magnesium-doped lithium niobate can be periodically poled with controllable distance between the inverted domains.

13.4 Fiber Growth Aspects

As stated previously, the LHPG technique is a very powerful tool for producing single crystals of various compounds, as shown in Fig. 13.15. Table 13.2 lists the different compounds produced using the LHPG technique. The following sections present practical features and aspects of the pulling process using the laser-heated pedestal growth technique, such as pulling of stoichiometric fibers, incongruently melt/evaporating

materials, and directional solidification on eutectic compounds.

13.4.1 Congruent Melting Fibers: The Search for Stoichiometry

Congruently melting materials are the easiest type of compound to pull successfully in single-crystal form.

Fig. 13.15a–h Single-crystal fibers of various compounds pulled by the LHPG technique: (a) SrTiO₃, (b) BaTiO₃, (c) GdAlO₃:Nd³⁺, (d) GdAlO₃:Cr³⁺, (e) La_{0.67}Ca_{0.33}MnO₃, (f) LaVO₄, (g) Al₂O₃ (sapphire), and (h) Al₂O₃:Cr³⁺ (ruby)

However, the stoichiometric line in the phase diagram is in reality a region (termed the existence region), i. e., it may extend over a certain homogeneity range [13.62].

Stoichiometry variations can impair the electric, ferroelectric, magnetic, optical, and other characteristics of these single crystals. For many compounds of interest, congruently melting compositions have been detected which are nonstoichiometric, thereby giving rise to unwanted effects such as thermodynamic instabilities, precipitates, intrinsic impurities, and deviations of the distribution coefficient of cations from unity [13.62].

Due to their technological importance, Li(Nb, Ta)O₃, YVO₄, and SBN (Sr_{0.61}Ba_{0.39}NbO₃) have been studied in order to achieve stoichiometry composition along the fiber length. Besides the composition variation of metal elements along the crystal growth axis, those compounds also present oxygen deficiency. Since the congruency originates from the defect structure of niobates, tantalates or vanadates, the oxygen vacancy also plays an important role in the growth of highly homogeneous crystals. In other words, metal oxides having different oxygen stoichiometry will possess different congruent compositions [13.56]. Another effect of the oxygen-deficient phases is that they can form solid solutions with their pentavalent variant, as was observed for YVO₄ by Erdei et al. [13.80]. These solid-solution formations cannot be eliminated by simple melt growth techniques. The oxygen deficiency can also slightly modify the Li:Nb, Li:Ta or Y:V stoichiometries in LiNbO₃, LiTaO₃, and YVO₄ during the growth processes. In this way, it is possible to verify that there is not one general precise value for the exact congruent composition in the niobate, tantalate or vanadate families. Erdei et al. identified that slightly oxygen-deficient SBN connected with Nb₂O_{5–x} creates a solid solution with the pentavalent niobium–SBN system [13.56, 62].

In order to grow high-quality single-crystal fibers with near-stoichiometric composition and high homogeneity along the fiber length it is possible to distinguish three basic strategies to achieve the goal of stoichiom-

etry control: seed compositions, self-adjusting melt composition, and pulling rate.

The seed composition strategy was already discussed in the seeding aspects of the LHPG technique (Sect. 13.2.1). Another strategy is to allow the system to self-adjust its melt composition. In the case of SBN fiber pulling, Erdei et al. observed that, after a transient composition at the beginning of fiber growth, the melt self-adjusted its composition and a high-quality fiber was obtained. Although a slightly off-congruent source rod composition was used the *composition-control system* of the LHPG technique modifies both the floating zone composition and the highly complex segregation effects, and can produce fibers that are homogeneous

in the growth direction [13.56]. However, the intensive convection flows generated in the molten zone are highlighted as responsible for the radial composition variations, as described earlier in Sect. 13.3.5. In another work, Erdei et al. also prepared YVO₄ single-crystal fibers, and the authors identified that the Y/V stoichiometry ratio was mainly caused by deficiency of oxygen due to vanadium oxide dissociation. However, it was Huang et al. [13.364] who was able to produce high-quality single-crystal fibers from stoichiometric-composition pedestals. The authors successfully applied pulling rates above 1 mm/min in order to avoid vanadium oxide dissociation and in this way obtained stoichiometric YVO₄ single-crystal fibers. The same

strategy was used by Burlot et al. [13.247] for growth of LiTaO_3 in order to avoid loss of Li_2O . The best results were obtained for pulling speeds of 0.7 mm/min. Nagashio et al. [13.232] also used high pulling rates in the LHPG technique to obtain near-stoichiometric LiNbO_3 fibers. They found that high pulling rates (4.1 mm/min) associated with a small molten zone length were the best conditions to avoid Li_2O evaporation, and thus to obtain stoichiometric fibers. Also, according to the Burton–Prim–Slichter (BPS) theory, the increased pulling rate leads the effective distribution coefficient (k_{eff}) to approach the value of 1 [13.59].

13.4.2 Incongruently Melting and Evaporating Fibers

An important characteristic of the LHPG technique is the possibility of growing incongruently melting and evaporating materials. Growth of incongruently melting bulk oxide single crystal is usually achieved by high-temperature solution growth, which is a slow and complicated technique. The source material in this technique must be rich in one or more elements to compensate for the incongruent melting. However in the LHPG system it has been shown that it is possible to grow such materials, $\text{Bi}_{12}\text{TiO}_{20}$ (BTO) for example, without the need for enrichment with excess Bi_2O_3 in the source composition. In other words, it is possible to grow incongruently melting materials from a source with the same composition as the grown fiber. According to Feigelson [13.8], the liquid composition in such growth experiments changes gradually until it naturally reaches the composition necessary for crystal growth, similar to the effect observed for SBN fiber growth (Sect. 13.4.1). This implies that, at the beginning of the process, the crystallizing solid must have a non-stoichiometric composition to allow the liquid phase to change gradually. With the LHPG technique it was possible to growth single-crystal fibers of BTO compound with 300–1200 μm diameter and up to 70 mm length (Fig. 13.16). The pulling rates typically used in

Fig. 13.16 The side of a $\text{Bi}_{12}\text{TiO}_{20}$ single crystal fiber grown from a stoichiometric pedestal, evidencing the natural face on the $[1\bar{1}0]$ crystallographic direction

this process were 6–18 mm/h, much higher than the few millimeters per day available with high-temperature solution methods.

By conveniently controlling the pulling and feeding ratio, it is also possible to grow materials with incongruent evaporation, such as Sr_2RuO_4 . The conventional method for growing Sr_2RuO_4 single crystals was floating zone melting, but due to the high evaporation rates of Ru_2O_3 , only single crystals of a few millimeters had been grown. Using the LHPG technique, and with a prereacted powder and then extruded source material with SrRuO_3 composition, it was possible to growth Sr_2RuO_4 single-crystal fibers up to 30 mm in length and 0.8–1.0 mm in diameter [13.279]. The best results were obtained with pulling rates of 0.3 mm/min with a feeding (source) rate of 0.4 mm/min. This again was only possible because of the high temperature gradients at the growth interface, allowing the growth velocities to be higher than in the conventional floating zone technique, and that a small amount of material stays at a high temperature for a short period of time, minimizing the ruthenium oxide evaporation.

13.4.3 Eutectic Fibers

The properties of materials are dependent not only on their composition, but also on their microstructure. In this way, phase distribution, size, and shape as well as interface characteristics play a crucial role in determining the behavior of composites [13.93]. The eutectic microstructure can be separated into three basic morphologies: lamellar, fibrous, and what is known as *Chinese script*.

The entropy of melting plays a very important role in determining the final microstructure of a eutectic. In 1966, Jackson and Hunt [13.365] demonstrated that irregular microstructures such as the *Chinese script* are formed during faceted–nonfaceted growth, in which one phase has high while the other has low entropy of melting. Eutectic compounds, despite the complexity of their microstructure, obey the following relationship [13.365]

$$\lambda_e^2 v = C, \quad (13.19)$$

where λ_e is the mean spacing between the phases, v is the pulling rate, and C is a constant.

The Al_2O_3 – $\text{ZrO}_2(\text{Y}_2\text{O}_3)$ system, called **ZA**, is one of the eutectic systems that have been systematically studied by the LHPG technique [13.87, 90, 92]. Farmer and Sayir [13.90] studied the fracture strength of 68 mol % Al_2O_3 in the ZA hypoeutectic composition

at varying Y_2O_3 content in fibers ranging from 1.0 to 1.8 mm in diameter. Their experiments showed that the Y_2O_3 composition has a major influence on the eutectic microstructure. Pure ZA eutectics have a lamellar microstructure at a pulling rate of 40 mm/h, although with the inclusion of Y_2O_3 the melt became constitutionally supercooled and a planar growth front in not maintained. Under conditions of large undercooling, the leading phase Al_2O_3 facets on the r -planes $\{1\bar{1}02\}$ and a transition from lamellar to ZrO_2 rod morphology occur. In this new condition, the fracture strength increases from 0.7 to 1 GPa. This increase is more strongly influenced by partial stabilization of the ZrO_2 than by the change in the phase morphology. With 1.1 mol % or less of Y_2O_3 the observed morphology shows excess Al_2O_3 accommodated in Al_2O_3 -rich colony boundary regions and formation of Al_2O_3 -rich facets on the fiber exterior in small-diameter (1.0 mm) fibers. With Y_2O_3 composition greater than 1.1 mol %, the system is highly supercooled and primary Al_2O_3 dendrites nucleate. The authors also observed, for compositions in the range 3.5–7.6 mol % Y_2O_3 , the formation of large amounts of $\text{Y}_3\text{Al}_5\text{O}_{12}$ within the colony boundary [13.90]. Peña et al. [13.94] pulled fibers with 1.5 mm diameter with a composition of 9 mol % Y_2O_3 . The authors reported that they were successful in producing fiber with highly homogeneous morphology. This was accom-

Fig. 13.17 Dependence of the mean spacing between the phases on the pulling rate of $\text{Al}_2\text{O}_3/\text{GdAlO}_3$. Only the *Chinese script* microstructure is present in all fibers on the right side of the vertical line (after [13.36])

plished by the use of very low pulling rate (10 mm/h), which in other words, increased the value of the ratio G/v , avoiding the constitutional supercooling condition. Francisco et al. [13.87] studied the influence of the processing conditions on the eutectic microstructure and reported a transition from coupled to dendrite growth at about 50 mm/h with axial gradient of 6×10^5 K/m, regardless of the rotation speed used.

Another eutectic explored by the LHPG system is Al_2O_3 -YAG. Pastor et al. [13.82] pulled 1 mm diameter fibers from pedestals containing 81.5 mol % Al_2O_3 and 18.5 mol % Y_2O_3 , the known eutectic composition. The fibers showed a *Chinese script*-type homogeneous microstructure. Due to the characteristics of its complex microstructure the hardness was fairly isotropic and the longitudinal strength of eutectics pulled at low and medium rates remained practically constant up to 1700 K.

The substitution of YAG by GdAlO_3 produced another interesting aluminate eutectic system ($\text{Al}_2\text{O}_3/\text{GdAlO}_3$) with the *Chinese script* microstructure. Andreea et al. [13.36] reported the pulling of $\text{Al}_2\text{O}_3/\text{GdAlO}_3$ eutectic fibers by LHPG technique using unreacted pedestals with a mixture of 77 mol %

Fig. 13.18a,b SEM photographs of (a) $\text{ZrO}_2(\text{CaO})\text{-NiO}$, and (b) transverse section of $\text{ZrO}_2\text{-MgO}$ (after [13.93]) ◀

Al_2O_3 and 23 mol % Gd_2O_3 . The average fiber diameter was $600\text{ }\mu\text{m}$ and the pulling rate ranged from 4.2 to 48.0 mm/h . In transversal analysis of the fibers, it could be observed that for pulling rates higher than 24 mm/h a transition from homogeneous to a complex regular microstructure appeared, with circular regions with larger GdAlO_3 phases, and even cellular arrangements with a fibrous pattern inside. Using pulling rates lower than 24 mm/h and with temperature gradients of $6 \times 10^5\text{ K/m}$, the high value of G/v prevented constitutional supercooling and fibers without the complex regular microstructure could be obtained. The Jackson and Hunt relationship [13.365] that holds for this compound was determined to be $\lambda^2 v = 40\text{ }\mu\text{m}^3/\text{s}$ (Fig. 13.17).

Orera et al. [13.93] explored the optical properties of the eutectics with regular microstructure to

be used as waveguide devices (Fig. 13.18). The eutectics have atomic-scale interfaces, producing sharp refractive index transitions between the phases, which lead to diffraction, interference, polarization effects, etc. Orera et al. also studied the waveguide effect of the fibrous microstructure of the eutectics. The authors showed that the $\text{CaF}_2\text{--MgO}$ eutectics can produce single-mode waveguides in the third optical window ($1500\text{--}1600\text{ nm}$). They also reported the cutoff wavelength, i.e., the most energetic light that can propagate in single-mode form, for the CaO--ZrO_2 ($\lambda_c = 1700\text{ nm}$), $\text{Al}_2\text{O}_3\text{--ZrO}_2$ ($\lambda_c = 500\text{ nm}$), and $\text{CaF}_2\text{--MgO}$ ($\lambda_c = 1300\text{ nm}$) eutectic systems. Since in the calcium fluoride eutectic light is guided by MgO fibers, it forms an optical-fiber bunch integrated in a crystal matrix which can be used for optical image transfer, giving a density higher than $40\,000\text{ pixels/mm}^2$.

13.5 Conclusions

The laser-heated pedestal growth technique (LHPG) has been presented as a powerful research tool for crystal growth of new and conventional compounds. In order to understand the state of the art of this technique, we report a historical background that led us to the beginning of the 20th century, when Baker and da Costa Andrade, one of Laue's and Bragg's coworkers, developed the first metallic single-crystal wires. One of the greatest breakthroughs in fiber research was, however, achieved by Fejer and coworkers with the introduction of an optical component (the reflexicon) to yield what is nowadays called the LHPG technique. This can be verified by the large increase in the number of papers published on the subject after the publication of Fejer and Feigelson's papers in the 1980s. The publication dynamics for laser-heated fiber growth over the last two decades shows that this technique is already well established, with more than 20 papers produced each year and more than 80 new and conventional different crystallographic matrices being produced. It must be noted that in this chapter only fiber pulling by LHPG technique was considered, which means that other fiber-pulling techniques such as the pulling down, melt extraction, and vapor reaction techniques were not included, which would certainly further increase the volume of scientific production.

The trends in the laser-heated pedestal technique can be separated into three basic lines. The first obvious trend is basic research into the fiber-pulling process, since the technique allows visualization of the molten zone and crystallization interfaces. In this way, it is possible to gain access to many solidifying parameters such as temperature gradients, interface shape, and contact angle. These are important, especially for very high melting point ($> 2500\text{ }^\circ\text{C}$) compounds, and are virtually impossible to measure in other conventional, crucible techniques. The second line is the miniaturization of some of today's devices by substituting bulk crystals with crystalline fiber. Along these lines it is possible to include the design of completely new devices based on the shape properties of fibers, such as high-temperature thermometers and infrared (IR) waveguides. Finally, with the approach of the data storage limit in semiconductor technology that could lead to holographic storage, and the need for new and efficient scintillators, ferroelectric compounds, and solid-state laser hosts, the most promising use of the laser-heated pedestal growth in the near future is its association with the combinatorial approach for new materials development. The LHPG technique can be used to test the possibility to grow large single crystals of the chosen compound and look more deeply into its physical properties.

Synthesis of

14. Synthesis of Refractory Materials by Skull Melting Technique

Vyacheslav V. Osiko, Mikhail A. Borik, Elena E. Lomonova

This chapter discusses methods of growing refractory oxide single crystals and synthesis of refractory glasses by skull melting technique in a cold crucible. It shows the advantages of radiofrequency (RF) heating of dielectric materials in a cold crucible and points out some specific problems regarding the process of growing crystals by directional crystallization from the melt and by pulling on a seed from the melt. The distinctive features of the method of directional crystallization from the melt are discussed in detail on the example of technology of materials based on zirconia, i. e., cubic single crystals and partly stabilized single crystals. It is shown that the size and quality of crystals are functions of the process conditions, such as thermal conditions under crystallization, growth rate, and chemical composition. We provide an overview of research on the structure, phase composition, and physicochemical properties of crystals based on zirconia. The optical, mechanical, and electric properties of these crystals make them suitable for a number of technical and industrial applications in optics, electronics, materials processing, and medicine. In this chapter, we also consider some problems regarding the synthesis of refractory glasses by skull melting technique. The physicochemical and optical properties of glasses are given and their practical applications in technology are discussed. We note that one of the better developed and most promising applications of skull melting technique is the immobilization of liquid and solid waste

(also radioactive waste) into solid-state materials by vitrification.

14.1 Overview

Refractory single crystals have a wide range of applications in modern technology. Successful development of fields and branches such as microelectronics, fiber

optics, laser techniques, metallurgy, and mechanical engineering would be impossible without elements based on refractory crystals and glasses as significant compo-

nents. In order to promote the development of refractory materials technology it is necessary to find solutions to a number of problems relating to obtaining materials of a required chemical composition with predetermined properties, including

- Development of crystal growth methods and material synthesis techniques at temperatures higher than 2000 °C
- Growing single crystals and casting glasses with perfect internal structure
- Obtaining ultrapure materials where the uncontrolled impurity content does not exceed 10^{-4} wt % and in some cases even 10^{-6} wt %
- Controlled synthesis of materials in oxidation–reduction gas environments
- High production efficiency with minimal harm to the environment

The main challenge is to provide a complex solution to these problems, i. e., in the ideal case the developed technology will meet all these requirements. It is our opinion that the technology surveyed in this chapter can provide a complex approach to the problems related to the production of refractory crystalline materials and glasses, even though it also has certain shortcomings. This technology is based on the skull melting (SM) method in a cold crucible (CC), which follows two main principles:

- Keeping the melt in a solid shell (skull) with a chemical composition identical to that of the melt
- An inductive (i. e., contact-free) method of heating the material

These principles were proposed by various scientists a rather long time ago; for instance, the method of melting metal in an arc furnace with a water-cooled metal plate has been known since 1905 [14.1]. Later on there appeared some work on the method of inductive melting of metals and semiconductors in a CC [14.2, 3]. In the 1960s French scientists published their research on the method of inductive melting in CC of specific refractory oxides (Al_2O_3 , ZrO_2 , Y_2O_3 , TiO_2 , and UO_2) and complex chemical compounds based on them [14.4–8]. After that a number of publications appeared on the inductive heating of glass in cooled quartz and ceramic crucibles for vitrification of radioactive waste [14.9], as well as on the synthesis of ultrapure glasses in cooled quartz crucibles for fiber-optic communication lines [14.10, 11]. At the same time, independent re-

search started at the Physical Institute of the USSR Academy of Sciences, aiming at developing technology for refractory materials production by the SM method. In the course of this research, appropriate equipment was designed and developed, conditions of melting and crystallization of various chemical compounds were systematically and thoroughly studied, and large-sized single crystals were grown from solid solutions based on zirconia and hafnia, as well as single crystals of rare-earth oxides, alumina, scandia, and yttria [14.12–15].

To date there have been quite a few publications discussing the modeling of inductive melting of dielectric materials in a CC. The basic properties of a thermal balance for so-called internal melting, which is very similar to SM, were discussed in [14.16, 17]. Some theoretical assumptions made in [14.16, 17] were applied to SM [14.18, 19], and this analytical model was used to account for quantitative description of losses in an RF coil and a crucible. The dependency between the form of a melted zone and the parameters of the system was calculated, a comparison with experimental data was made, and the stability of a melted zone was investigated [14.18, 19]; similar research is reported in [14.20–22]. The experience has shown that the new technology has a number of definite advantages and can successfully be used to synthesize refractory materials, including single-crystal growth. Some of these advantages are:

- There is no upper limit on the temperature (up to 3000 °C and higher).
- There is no contact with alien chemical substances and, therefore, the obtained materials are exceptionally pure. The purity of the resulting material can even exceed the purity of the original material in terms of some impurities (either volatile matters or those which are easily segregated during crystallization).
- The process can be carried out in any atmosphere, including an oxidizing one (air or oxygen).
- Any type of chemical reaction with the melt is possible, in both single-phase and multicomponent systems.
- Melting process can be interrupted or carried out continuously, without any restrictions on the melt volume.
- There are no specific requirements on grain-size composition of the initial materials.
- It is a waste-free technology, since the crystalline scrap from previous melting processes and other waste can be remelted.

- It becomes possible to obtain a large volume of melt, which facilitates convective mass and impurities transport and leads to better-quality single crystals.
- The melt composition can be changed during synthesis by adding different components to the melt via its open surface.

The most striking result of the developed **SM** technology is the industrial technology of growth and production of crystals based on zirconia. This is the only existing method for zirconia crystal production for

industrial purposes. Each month several hundred tons of crystals are manufactured, with production concentrated mostly in the USA, China, South Korea, Russia, and Taiwan. More than 90% of grown crystals are used in jewelry and the rest is used in some technical applications. In this chapter we give an overview of experimental and theoretical research on **SM** in a **CC** and the results of this research, with special attention paid to the technology of zirconia-based single-crystal growth and the application of this method to glass synthesis.

14.2 Techniques for Growth of Single Crystals in a Cold Crucible

The development of the **SM** technique of nonmetal materials in a **CC** promoted progress in the field of technology of refractory materials, in particular single crystals. As has already been mentioned, the technique allows the melt to be held at very high temperature (up to 3000 °C or higher) to keep it in a stable state for crystallization under controlled conditions. During the last 40 years of the development of this technique a large variety of single crystals of refractory oxides and compounds have been grown, their properties have been

investigated, and some industrial technologies and special equipment have been developed. The procedure of **SM** and crystallization from the melt under direct radiofrequency (**RF**) heating has been described in many studies [14.15, 23–25] and consists of several steps: (1) start melting, (2) formation of the main volume of the melt, (3) setting the melt–solid shell system in equilibrium (homogenization), and (4) crystallization of the melt (Fig. 14.1).

The necessity for start heating of dielectric materials and its practical implementation are discussed in detail in [14.25, 26]. Normally the metal used to initiate the start heating is the same as in the initial oxide charge. The metal and the surrounding charge are heated by the absorption of **RF** energy and the exothermic oxidation of the metal. In each particular case, the exact contribution of each process depends on the physicochemical properties of the metal used. Moreover, the process is affected by the conditions under which the start melting is carried out, i. e., the composition of the gas atmosphere, the position of the seed metal in the charge, the amount of seed metal, the particle size of the initial charge powder, etc. The time of start melting is largely determined by these factors. Graphite is rather frequently used in start melting because it completely oxidizes in air without any contamination of the melt. Being economical, this technique is very often employed in industrial production of many refractory materials and crystals. As a rule, bar-shaped graphite pieces are linked to obtain a ring with diameter smaller than that of the **CC**. Graphite is also used for melting complex oxide compounds and glasses, when it is sometimes positioned in the refractory ampoule, made of, for example, quartz, in the form of a heating rod. The rod is inserted into the center of the crucible filled with the

Fig. 14.1a–d Main stages of crystal growth technology in a cold crucible: (a) start melting, (b) formation of the main volume of the melt, (c) homogenization, and (d) crystallization

initial powder charge. As the initial volume of the melt increases in the crucible, the rod is drawn out by means of various tools.

After start melting is complete, the melt volume should be increased gradually by the melting of ambient solid phase of the charge. The charge is usually composed of either oxide powders or their mixture with previously melted material. The melt volume increases until the charge in a CC is melted completely except for a thin layer of powder adjusting to the walls of the CC. This layer with a thin layer of crystallized melt together forms a polycrystalline solid (shell) or skull. Additional portions of the charge can be gradually poured into the melt until the desired volume of melt is reached. The use of either previously melted or preliminary compacted materials allows the desired volume of the melt to be achieved without additional pouring. In this case all the material is charged into the CC at once and the start melting occurs in the upper part of the charge, while the charged crucible is set at its lowest position. As the melt forms, the crucible is moved upwards to melt the whole charge, until the highest position is reached. This technique is less laborious but more time consuming and, thus, is less economical with respect to energy consumption.

When the volume of the melt reaches the desired value, the melt is exposed for a certain time under a constant energy input in order to achieve thermal and spatial equilibrium between the melt and the skull. The principal feature of the resulting stationary state of the system is a constant volume of the melt, i. e., the immobility of the melt–solid phase (skull) interface. The conditions of the phase equilibrium are discussed in [14.12]. Despite some rough approximations made in the analysis, it provides a simple and clear evaluation of the peculiarities of the phase equilibrium in the melt–solid system in a CC (Fig. 14.2). The following approximations are made in the analysis:

1. The temperature of the melt is equal over the volume, except for a thin layer adjacent to the skull (assuming complete stirring of the melt).
2. The temperature (T_L) at any point of the melt–solid interface is equal to the melting point and does not change.
3. The RF field energy is absorbed by the melt only and the field is uniform inside the inductor.

The amount of heat given off by the melt to the surface of the solid phase (Q_1) can be expressed as $Q_1 = \alpha(T_M - T_L)F\tau$, where α is the heat emission co-

Fig. 14.2 Illustration of melt–solid equilibrium in a cold crucible

efficient, T_M is the temperature of the melt, T_L is the temperature at the solid–liquid interface (which equals the melting point), F is the heat-emitting surface, and τ is time. The amount of heat transported through a solid layer of thickness σ_s and thermal conductivity λ can be expressed by $Q_2 = \lambda/\sigma_s(T_L - T_0)F\tau$, where T_0 is the heat carrier temperature. For stationary conditions $Q_1 = Q_2$, i. e., $(\lambda/\sigma_s)\alpha = (T_M - T_L)/(T_L - T_0)$, where $(T_M - T_L) = \Delta T$ is the parameter characterizing the overheating of the melt. If we assume λ , α , and T_0 to be independent of σ_s , then $\sigma_s \Delta T = \text{const}$.

The above analysis leads to the following conclusions:

- An essential feature of the skull melting technique is the necessary overheating of the melt ΔT , the value of which greatly affects the process of crystal growth in a CC (if $\Delta T \rightarrow 0$, then $\sigma_s \rightarrow \infty$).
- There is always a solid skull in a CC because complete melting of the solid phase requires infinite overheating (if $\sigma_s \rightarrow 0$, then $\Delta T \rightarrow \infty$).
- Increasing or decreasing the melt temperature (T_M) changing the skull thickness σ_s .
- Convection of the melt determines the value of the heat emission coefficient α , thus affecting the phase equilibrium.
- Any process in the skull resulting in a change of its thermal conductivity (e.g., sintering or fusion penetration) will disturb the phase equilibrium and therefore cause variation in either the melt temperature (T_M) or the skull thickness (σ_s).

After the thermal equilibrium in a CC has been established, crystallization of the melt takes place. The crystallization can be carried out by various techniques. For producing molten polycrystalline materials a fast mass crystallization is quite suitable. Single-crystal

growth is performed either by means of a directional crystallization, which is similar to the Bridgman–Stockbarger technique, or by pulling a seed similarly to in the Czochralski or Kyropoulos growth techniques. Applications of the other methods of single-crystal growth (e.g., crystallization from the flux solution or Stepanov technique) are also possible. The majority of single crystals are produced by either directional crystallization or by pulling a seed from the melt in a CC.

14.2.1 Directional Crystallization of the Melt

Most single crystals grown from a CC are produced by means of directional crystallization of the melt. The choice of this technique is motivated by its relative technical simplicity, which does not require any additional heat sources or complicated design of the thermal unit. Directional crystallization is usually carried out by lowering the crucible containing the melt out of the induction coil at a certain rate. Electromagnetic interaction between the lower part of the charge and the induction coil decreases as this part moves away from the inductor, so the released power also decreases. Gradual cooling then results in the crystallization of the melt at the bottom of the crucible. When using large-volume CCs, it is more convenient to conduct directional crystallization by moving the induction coil upwards, the container being fixed; this prevents technical problems associated with the design of the drive assembly for the heavy (> 1000 kg) charged crucible, and should ensure reliable operation and uniform crystallization rate in order to grow good-quality crystals.

Less frequently, crystallization is conducted by gradual reduction of the power. This procedure is less reliable, as it may lead to spatial instability and uncontrollable solidification of the melt [14.15–18]. Therefore, it is suitable only for crystallization of high-stability melts. The melt stability depends on the electrical and thermophysical properties of the material. Thus, to ensure a reliable and economical process, it is desirable to use melts which have sufficiently high electrical conductivity over a wide range of temperatures and with low thermal conductivity of the solid phase. The feasibility of SM for crystal growth also depends on a number of physicochemical properties of the material used. High evaporation rates of melt components may reduce the volume of the melt, causing the system to become unstable or resulting in uncontrolled crystallization of the melt. However, more frequently, volatility of a certain component causes a deviation

from stoichiometry of the grown crystals. If this is the case, it is necessary either to correct the melt composition during growth or to use ambient atmospheres that prevent this deviation.

A CC usually consists of isolated sections and has gaps, so in the case of melt penetration, the melt can leak out, which can disturb the crystallization process. Leakage is prevented by the surface tension of the melt, which is determined by the surface tension coefficient, the size of gaps between the sections of the crucible, and the wettability of the wall. Therefore, it is easier to work with melts, possessing high surface tension. For single-crystal growth, direct crystallization in a CC has a number of advantages compared with other well-known crucible-less techniques (e.g., Verneuil or floating-zone technique); for instance, this method allows a considerable volume of the melt to be created, which promotes convective transfer of the main constituents and impurities and provides better quality of crystals. In addition, this method can be used to grow crystals in any atmosphere. The open surface of the melt makes it possible to vary the melt composition by adding various components and facilitates purification of the melt of volatile impurities and gases. However, single-crystal growth by directional crystallization in a CC faces some general difficulties, mainly associated with peculiarities of the direct RF heating of dielectric materials. With this method of heating the melt itself, being a transient power load in the oscillatory circuit of the RF generator, is a heat-absorbing body. The interaction between the load (melt) and the generator is rather complicated. Melting and crystallization occurring in the skull result in changes of the volume and electrical conductivity of the melt, which affect operation. This is problematic for rigorous control of the input power required to sustain the stability of crystallization. On the one hand, if the input power drops below a certain critical point, this may lead to loss of coupling between the melt and the RF field and, consequently, spontaneous crystallization. On the other hand, if the melt is overheated (i. e., excess input power), this results in melt penetration through the skull, leakage of the melt through the gaps between the CC sections, and disruption of the stability of crystallization (up to complete interruption of the process). Another control problem relates to the absence of visual monitoring of the process and direct measurements of the temperature of the melt and crystals during the growth. The high melting temperatures of the materials usually processed by this technique (such as zirconia, with a melting point of $\approx 3000^\circ\text{C}$) and the presence of the RF field hinder

any temperature measurements, except irradiative ones. Only the melt surface lends itself to direct observations and measurements, when the upper thermal screen (or core) is removed.

Just after the crystallization has been completed, annealing of the crystals is carried out directly in the growth furnace. Annealing is an important stage of the process, necessary to relieve any residual stress in order to prevent fracturing of the crystals. In a conventional growth furnace, there is usually a zone with a certain temperature gradient, where the crystals can slowly cool to the ambient temperature. This, however, becomes impossible when using direct RF heating for crystal growth because the electric conductivity of materials sharply decreases in the process of crystallization. The absorption of the RF field power decreases too, which results in uncontrollable cooling of grown crystals. The cooling rate depends on the volume of the crystallized material (i. e., its thermal inertia). Given that crystals are placed in a water-cooled crucible, the cooling rate of the crystal in zones adjacent to the wall is significantly higher.

The method of directional solidification in a CC essentially differs from the conventional *hot* techniques of crystal growth, e.g., the Bridgman–Stockbarger method, in which nucleation occurs only at the interface between the crystal and a considerable volume of the melt, followed by directional crystallization over a temperature gradient field. In these furnaces a certain gradient of temperature is created and maintained during the growth. The growth usually starts with complete melting of the charge in a crucible, and then, at the stage of initial nucleation, several crystals are formed. Further growth of one of the nuclei at the *crystal–melt* interface

is performed by various techniques: a conical bottom, a capillary or constrictions on the bottom, and seeding. The task of growing large and good-quality crystals by this method is solved empirically by appropriate selection of crucible shape, temperature gradients, and the rates of lowering the crucible or cooling of the furnace. In directional crystallization in a CC the melt is in permanent contact with the skull of the same composition formed on the bottom and walls of the crucible. Therefore, polynuclear crystallization takes place. Crystallization begins in the lower part of the crucible from the crystal grains of the skull. As crystallization proceeds, the number of crystals is reduced considerably due to selection according to growth rate. As a result, a bulk of column-shaped single crystals is obtained. It is impossible to use any device to limit the quantity of crystals growing from the bottom and the walls of the crucible because of the very high temperatures and RF field. In general, seed crystals allow to increase the size and decrease the amount of growing crystals, but in practice this is rather problematic. Therefore, the quantity and size of the crystals are determined by the composition of the melt and the growth process conditions.

The peculiar distribution of temperature fields inside a CC is another important feature of the method. On the one hand, the distribution is determined by the RF field energy release in the melt, which depends on the melt properties at a current temperature, and on the other, by heat removal through the walls and bottom of the crucible maintained by the heat carrier (water). Growing good-quality crystals is determined by proper control of the temperature and temperature gradients in the melt and solid phase. Therefore, the distribution of temperature fields in a CC is extremely important. The patterns of temperature distribution both at the surface and inside the oxide melt under direct RF heating, as well as a number of technological conditions influencing these patterns, have been studied [14.27] using glass-forming melts in the temperature range 1000–1500 °C as a model system. The temperature distribution was shown to be determined by both the process parameters (absorbed RF power, position of a CC with respect to the induction coil, and the size and shape of a crucible) and the properties of the melt (temperature dependencies of the viscosity and electric conductivity). Typical temperature distribution patterns in the glass-forming melt under direct RF heating in a CC are presented in Fig. 14.3 for various viscosities. As this figure shows, a decrease in melt viscosity (most of non-glass-forming oxides) results in a signifi-

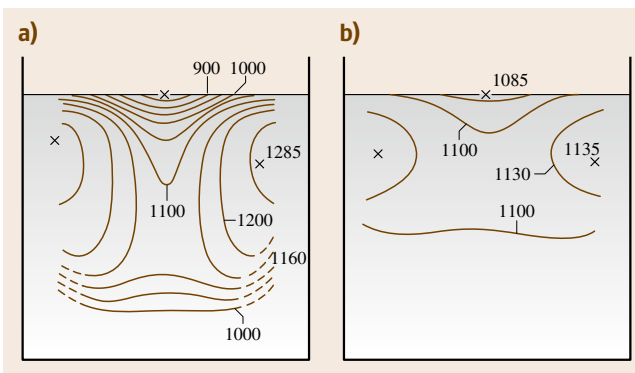

Fig. 14.3a,b Temperature distributions (°C) in oxide melts with different viscosities: (a) 45.6Na₂O + 54.4SiO₂; (b) 55.4Na₂O + 44.6SiO₂

cant decrease of the temperature gradients in the melt, the general pattern of temperature distribution being the same.

A simplified model can help explain the temperature distribution patterns under direct RF heating. Most of the RF energy is released in a certain active layer of the melt, the thickness of which depends on the RF generator frequency and the electric conductivity of the melt, whereas the rest of the melt is heated by conduction of heat from this part. This type of heating can be roughly compared to the one produced by a virtual heat source in the form of a hollow cylinder placed into the melt. The height and diameter of the source are determined by the induction coil height and RF field penetration depth (the thickness of the active layer), respectively. It is clear that, in this model, the radial temperature gradients will be determined by the diameter of the CC and by the input power, and the axial ones by the position of the melt with respect to the induction coil and the heat losses.

For the directional crystallization method of crystal growth, the temperature distribution in the lower part of the melt controlling the crystallization front is of primary importance, but there are no data available for refractory materials. Nevertheless, even on the basis of a model, some conclusions could be made, which were later confirmed in practice. Thus, the maximum temperature is achieved at the level corresponding to the center of the RF coil, while in the upper and lower parts of the melt the temperature is lower due to the heat sink through the lower part of a crucible and heat losses from the surface of the melt. The ratio of heat flows removed from the top and bottom of the crucible determines the position of the maximum temperature zone, related to the melt depth and the values of the axial gradients. At the same time, the axial gradients are higher in the area that corresponds to the RF field energy release (i. e., at the periphery) than in the central zone. Such a temperature distribution results in an increase of temperature in the melt layer above the crystal bulk growing from the bottom with increasing height. Consequently, thermal convection in the melt is hindered. The effect of electrodynamic stirring depends on the applied RF field frequency and is negligible for frequencies of 0.5–10 MHz [14.26]. The most intensive convective stirring occurs in the upper part of the melt. Radial temperature gradients in the heating zone suppress growth of crystals from the walls of a CC into the melt. However, if the melt is overheated, the crystallization front becomes concave and shifts below the heating zone (i. e., lower than the RF coil). This is associated with in-

tense growth of crystals adjacent the skull and leads to an increase in the total number of the crystals, although the crystals become smaller. In order to suppress this growth, it is desirable to reduce overheating to a minimum and to maintain the heat sink from the bottom so that the crystallization front is either in the active heating zone or as close to it as possible. This is favorable for decreasing the total number of nucleating crystals and improving the quality of single crystals [14.28–31], because it brings the crystallization front near to the zone of intense convective stirring.

The following question thus arises: how to control the temperature distribution in the melt. First, this can be done by changing the pattern of energy absorption in the melt, which is largely determined by the value of the resistivity of the melt, its temperature dependency, and the RF field frequency. The former two parameters are properties of the material itself and so are predefined. The optimal electromagnetic field frequency is also predetermined by the electric properties of the material; it can be varied within a narrow range, but these variations do not significantly affect the temperature fields in the melt. For example, if the resistivity of the melt is $0.1 \Omega \text{ cm}$ then frequency variation from 5 to 1 MHz results in changing of the penetration depth from ≈ 0.7 to $\approx 1.6 \text{ cm}$. Even for small crucibles (e.g., 10 cm in diameter) this change could not significantly influence the values of temperature gradients. It is also possible to change the electromagnetic field configuration by changing the RF coil design, insertion of additional short-circuited turns, magnetic enhancers, etc. [14.25, 26, 31].

In our opinion, the simplest and most efficient way to control temperature gradients in the melt is to use those means that involve heat removal from the melt through the walls and the bottom of the crucible, as well as from the melt surface. To control heat removal through the walls of a cold crucible and from the melt surface heat shields are used. In order to keep the crucible bottom warmer, a part of the charge at the bottom is not subjected to melting at the stage of formation of the main volume of melt. This part is located below the heating zone and has the same composition as the main charge. This thermal shield decreases heat loss through the crucible bottom, balances the radial temperature gradients in the melt, reduces axial gradients in a growing crystal, decreases electromagnetic losses related to the absorption of energy by a massive metal bottom at start melting, and affects nucleation and degeneration of crystals in polynuclear crystallization. Low axial gradients and uniform thermal properties at

the melt–solid interface help to decrease the number of nucleated crystals and to increase the size of individual single crystals.

The upper thermal shields are formed when the melt volume formation is nearly completed. Thermal radiation from the melt surface at high temperatures has high intensity, which leads to fast sintering of the powder charge above the melt. This sintered layer (crust) functions as an upper thermal shield. Such insulating layers of sintered material with composition identical to the melt readily occur in small-diameter cold crucibles. It is much more difficult to form the upper thermal shield in crucibles with larger diameters, although the role of such a shield becomes more important for crystal growth in large-diameter crucibles because the upper thermal shield decreases heat losses associated with radiation, increases the surface temperature, and consequently reduces the probability of spontaneous crystallization in the upper part of the melt, which is frequently the case in refractory melts. Reducing the heat losses results in better performance by decreasing the electricity cost, which is of primary importance for high-capacity installations. Surface heating (skin effect) and high temperature gradients in **SM** require special technological procedures for balancing thermal fields in the melt in order to achieve uniform melting and stable crystal growth over the whole diameter of the crucible. If the input power is insufficient and efficient upper thermal shielding is absent, the central part of the melt becomes overcooled, which results in the formation of small and imperfect crystals in this area. In the worst case, the material in the central part of a crucible remains unmelted or crystallizes rapidly.

In the absence of shielding, low radial and high axial temperature gradients in the melt and in growing crystals lead to the formation of many small crystals, whereas large-sized single crystals are desirable. It is possible to control the ratio between axial and radial gradients by applying thermal shielding in the top and bottom parts of the melt, thus optimizing the gradients for growing large-sized single crystals. Appropriate selection of the thermal conditions is usually carried out experimentally because of the difficulties in regulating melting and crystallization in this method. Moreover, thermal shields help to increase the mass of the charge in a cold crucible, and, consequently, to slow down the cooling of the crystals after growth to prevent fracturing in large crystal bulks. The shape of a **CC** influences the temperature distribution inside a crucible, and hence the thermal conditions of crystal growth. If the crucible diameter is increased while the penetration depth and

input power are kept constant, then the radial gradients are reduced, leading to the formation of a convex or flat crystallization front. With constant heating parameters (frequency and power) and physical properties of the melt (electric conductivity and viscosity), changing the crucible diameter-to-height ratio affects heat removal from the growing crystals. The ratio of the melt volume to the square of the cooling surface decreases with increasing **CC** diameter. This reduces energy loss through the walls of a crucible and makes the process more economical. Heat removal from the growing crystals at the bottom mainly occurs through the bottom and side (lateral) walls in the lower part of the charge below the active heating zone. Therefore, the amount of heat removed from the growing crystals is reduced with the increase of crucible diameter for the same reasons: given that the height of this part remains the same, the larger the crucible diameter, the less cooling surface (through which the heat transfers from growing crystals) there is for a unit volume of solid phase.

Thus, there are two important factors for growing crystals from the melt in a **CC**: first, the power released in the melt should be accurately determined and correlated with the volume of the melt, and second, there is a need for proper control of the heat removal through the bottom of the **CC** and via the surface of the melt. Optimizing these parameters allows the shape of the crystallization front and its position with respect to the active heating zone to be varied. Unfortunately, as mentioned above, some of the processing parameters in a **CC**, such as the temperatures in the melt and in the solid phase, the melt volume, and the crystallization rate, are extremely difficult to control. These parameters can only be assessed by the final results of the crystallization after the process has been completed. Some attempts have been made to develop techniques that can provide indirect but reliable data on the melting directly in the course of the process. Continuous monitoring of the **RF** generator parameters combined with analysis of the generator loading status enables an elucidation of the mechanisms occurring in a **CC** [14.32–36].

To date a considerable variety of single crystals of simple and complex oxides and oxide solid solutions have been grown by directional crystallization. The conditions of crystallization and the dimensions of the crystals grown by this method are reviewed in [14.23]. It has been shown that the oxides of transition metals have the necessary electrical and thermophysical properties at high temperatures, which makes them suitable for **RF** heating, melting, maintaining in the molten state, and

further crystallization in a CC. CoO, Fe₃O₄, and TiO₂ single crystals up to 1–3 cm³ have been grown [14.37]. The scope of the technique has been demonstrated by magnetite single-crystal growth [14.38], before which good-quality magnetite (Fe₃O₄) single crystals were grown in platinum crucibles by the Bridgman technique. However, this approach was expensive since, following growth, the crucibles were cut to release the crystal, and, moreover, the crucibles were destroyed because of the diffusion of iron into the platinum. Thus, SM has obvious advantages in this case. In order to maintain the oxygen stoichiometry of magnetite it is crucial to create an atmosphere with a certain oxygen activity and to keep it under control. To solve this problem, the process was carried out in a CO/CO₂ buffered atmosphere with a fixed fugacity of O₂. The growth process consisted of two stages. In the first stage the charge is melted in air up to a desirable volume, and in the second stage the chamber is evacuated to allow the gas mixture to flow through it. The melt was kept in this atmosphere for 1.5 h to achieve equilibrium conditions, and then the crucible was lowered. A drop in the growth rate to 7.5 mm/h was mentioned to be necessary to attain the equilibrium between the melt and the gas phase and to grow larger crystals. Similar conditions were required to grow monoxides of some transition metals (Mn_{1-x}O, Co_{1-x}O, Fe_{1-x}O, and Ni_{1-x}O) with interesting electrical, optical, and magnetic properties, which can vary with the oxygen stoichiometry. The equipment used for growth in a CC was the same as in the previous case. After studying the effects of atmosphere on the phase composition of single crystals of transition-metal monoxides it was established that the excess of oxygen in the Fe_{1-x}O melt led to the formation of Fe₃O₄ inclusions, whereas metallic inclusions M⁰ occurred under a relatively reducing atmosphere. The importance of crystal annealing at subsolidus temperatures, which improves homogeneity of the crystals and completely eliminates the magnetite phase, was also demonstrated in these studies. With an adequate buffer oxygen atmosphere 1 cm-long (Fe₃O₄)_{1-x}(FeTiO₄)_x single crystals were grown. The atmosphere was controlled throughout the process, including the melting stage. Studies on the phase composition of grown crystals proved this method to be applicable to the growth of ferrite crystals of any composition. The same facilities and technology were also used to grow Ln₂NiO₄ (Ln = La, Pr) single crystals. Later on, single crystals of high-temperature superconductors [14.20, 39], several complex oxides (e.g., CeO₂-Y₂O₃) [14.40], oxide eutectics [14.41], and

other oxide compounds and compositions were synthesized and studied [14.42].

14.2.2 Crystal Growth by Pulling on a Seed from the Melt in a Cold Crucible

The method of crystal growth by pulling on a seed from the melt (Czochralski technique) in a hot crucible has been widely and successfully used for a variety of oxide crystals. Its application is conditioned by a strictly defined temperature distribution in the melt and at the crystallization front, as well as by a constant temperature at the crystallization front. The process of crystal growth by SM is of a great interest but it is associated with the some principal difficulties discussed above. The temperature distribution in the surface area of the melt is of primary importance for crystal growth by pulling on a seed. The isotherm patterns (Fig. 14.3) show the temperature distribution in the melt. Temperature gradients in the melt can be changed by varying the position of the RF coil with respect to the melt surface or by adjusting the input power. There are various additional factors affecting the formation of temperature gradients in the melt, such as optimizing the shape and the dimensions of a crucible, setting the optimal frequency, using thermal shields or additional heat sources, RF coil design, and some other parameters.

Let us now consider some practical applications of single-crystal growth by pulling on a seed from a CC. The synthesis of corundum and ruby single crystals was the first important scientific and practical result using this technique [14.12, 31, 43]. One of the conditions required for single-crystal growth by pulling on a seed was established to be the following: the specific heat flow from the melt though a crystal has to exceed the specific heat losses from the open surface of the melt. Thermal shields above the melt were used to decrease the heat losses associated with radiation. Besides, a cup-shaped crucible and RF coil were used to improve phase stability and to prevent crystal growth from the skull at the crucible surface caused by changing the input power (Fig. 14.4) [14.31]. The technique was used to grow ruby and corundum single crystals of various orientations, up to 160 mm in length and up to 35 mm in diameter. The pulling rate was in the range of 10–30 mm/h with seed rotation speed of 20–140 rpm.

The method of forming temperature gradients at the melt surface by means of thermal shielding was also applied for growing SrTiO₃ [14.44, 45] and Bi₁₂GeO₂₀ [14.46] single crystals. The Bi₁₂GeO₂₀ crystals were grown in a tubular crucible of 90 mm

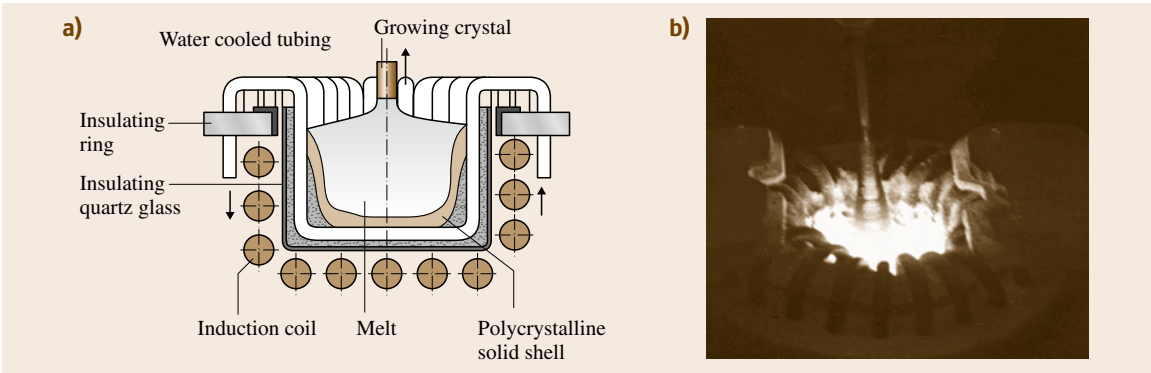

Fig. 14.4a,b Schematic of the unit for growing Al_2O_3 crystals from cup-shaped cold crucible (a) and photograph of growing crystal (b)

diameter and 60 mm height. The scheme of the heating unit for crystal growth is shown in Fig. 14.5.

The thermal and electrophysical properties of the melt allowed for adjusting the temperature by varying the input power over a wide range of values, while keeping the phase stability undisturbed. The consistency of input power supply was ensured by anode current stabilization. Convectional flows were observed on the melt surface. The intensity of the flows decreased when the input power was decreased, the convection pattern on the surface became regular, and the flows were oriented from the periphery to the center. Thermal shields provided more stable convection patterns, which made the intensity of the flows decrease. Figure 14.6 illustrates the temperature distribution on the melt surface measured by a pyrometer according to the observed convective flow pattern.

The grown crystals were up to 15 mm in cross-section and up to 100 mm in length (Fig. 14.7).

Fig. 14.5 Schematic of the unit for growing $\text{Bi}_{12}\text{GeO}_{20}$ crystals

In some cases the crystals were faceted while being grown, although crystal edge outlets of the fourth-order symmetry at the crystal surface were more frequently

Table 14.1 Concentration of copper in Bi₁₂GeO₂₀ crystals grown in a copper water-cooled crucible

Material	Concentration of Cu, wt%
Initial charge	$1 \times 10^{-2} \pm 5 \times 10^{-4}$
Skull	$9.3 \times 10^{-2} \pm 1.6 \times 10^{-2}$
Crystal top	$1 \times 10^{-1} \pm 2 \times 10^{-2}$
Crystal center	$7.5 \times 10^{-2} \pm 1.3 \times 10^{-2}$
Crystal bottom	$1.4 \times 10^{-2} \pm 2.5 \times 10^{-3}$

observed. Bi₁₂GeO₂₀ crystal grown in platinum crucibles is associated with the occurrence of platinum macroinclusions up to 0.5 mm. These inclusions are due to the chemical activity of the melt, which destroys the crucible surface, and to the metal particles becoming entrapped by a growing crystal. If a CC is used, this problem does not arise. However, X-ray spectral analysis revealed the presence of Cu (the material of a cold crucible) in crystals (Table 14.1). The measured concentration of Cu in the skull and in crystals was somewhat higher than in the initial charge and this was shown to be dependent on a number of technological parameters, such as overheating of the melt during start melting and during crystal detachment, the number of remeltings of the crystallized melt (the recycling factor), and the duration of growth. The presence of Cu did not result in inclusion formation and did not distort the optical homogeneity of crystals. A study of the optical properties of crystals revealed no influence of small copper impurities on the main properties of the material.

Another method for temperature fields formation in the melt was proposed in [14.47] for Nd₃Ga₅O₁₂ crystal growth. The growth was associated with significant turbulent convection on the melt surface. To suppress the convection and maintain the necessary radial temperature gradient, a *double-crucible* technique was applied, which consists of the insertion of a split iridium cru-

cible into the melt. On the bottom of the CC there was an iridium ring, which was heated by an additional RF coil. The ring was used to produce a start melt and as an additional heating source to ensure a constant volume of melt during growth. The technique allowed Nd₃Ga₅O₁₂ crystals of 35 mm cross-section and 90 mm length to be grown, the quality of which was comparable to that of crystals grown from heated crucibles by Czochralski technique.

An interesting development of the SM technique is presented in [14.48], which proposes to combine direct RF melting with radiative heating of the melt surface. Start melting is carried out by means of three powerful optic concentrators with xenon arc lamps used as light sources. The CC can be moved vertically or rotated. The radiation from these three light sources makes it possible to control the thermal field pattern in the melt by changing the position of the focal spot with respect to the axis of the crucible rotation and by adjusting the radiative power. There are alumina thermal shields and a platinum electric resistance furnace above the melt, which help to decrease the temperature gradients in the pulled crystal and the performance of subsequent annealing. Radiative heating sources in this model allow to form certain thermal patterns in the melt at a certain radiative-to-RF heating power ratio, which facilitates crystal growth by pulling on a seed. The technique was applied to grow MnZnFe₂O₄ crystals. The SM method for crystal growth is very promising, primarily for the synthesis of new refractory compounds (in the form of crystals) from the melt. However, the analysis of thermal fluxes in the melt and the development of methods to monitor and control the process to achieve a certain thermal field configuration remain the most complicated problems in this growth technique. This might be the reason why there are so few publications devoted to crystal growth by pulling on a seed from a CC.

14.3 Growth of Single Crystals Based on Zirconium Dioxide

Crystals of pure ZrO₂ are used very rarely because of destructive phase transformations. However, it was shown [14.49] that stabilizing the cubic phase by adding MgO, CaO, Sc₂O₃, Y₂O₃ or CeO₂ could prevent these phase transformations. In this case a metastable cubic solid solution with fluorite structure is formed at room temperature.

The high melting point (2700–2800 °C), the high chemical activity of the melt, and the occurrence

of polymorphic transformations made the growth of ZrO₂-based single crystals very difficult. That is why single crystals of pure ZrO₂ were obtained by low-temperature techniques such as flux growth, vapor deposition or hydrothermal method [14.50–54]. These processes are of a very long duration, while the size of the crystals obtained is rather small. Single crystals of solid solutions based on ZrO₂ were grown from the melt by crucible-free techniques (arc and floating-zone

melting) [14.55–59]. However, large-scale industrial production of ZrO_2 -based single crystals became possible only when the above-described SM method was applied. During the development of the method and its application for single-crystal growth, the first publications on the synthesis of ZrO_2 -based single crystals appeared [14.7, 12, 31, 60–62].

Research on some properties of single crystals of cubic solid solutions based on ZrO_2 (CZ) showed that these crystals possess unique optical, mechanical, and electrical characteristics, namely, they are optically isotropic, have high refraction index $n_d = 2.15 - 2.2$, and are transparent in the range 260–7500 nm; these crystals are very hard (8.5 by Moos), have a high melting point (2700–2800 °C), and demonstrate ionic conductivity at temperatures above 300 °C [14.13, 15, 31]. This combination of properties makes CZ crystals promising materials for many technical and industrial applications, including optical, electronic, instrument-making, and high-temperature techniques.

The first practical application of CZ crystals was in jewelry. The similarity of CZ's refractivity index to that of diamond and its high dispersion cause a special play of light under various lighting conditions. These properties make CZ crystals one of the best materials for the imitation of diamond. The possibility of crystal growth of various colors enables the imitation of other natural gemstones, as well as the creation of new gemstones of original colors. Development of the industrial technology, the creation of the first apparatus for crystal production, and the production of the first crystals were accomplished in the Physical Institute of the Academy of Sciences of the USSR (FIAN) as early as the beginning of the 1970s. Exactly this application gave great impetus to the setting up of the industrial production of these crystals and the creation of new equipment for RF heating. Industrial technology for the production of CZ crystals was first elaborated in Russia in FIAN. Mass production of these crystals, which were given the name *fianites*, was already organized at the beginning of the 1970s. In most countries these crystals are known as *cubic zirconia*. World production of CZ crystals for jewelry is inferior only to that of silicon and synthetic quartz crystals, thus occupying the third place.

The following problems remain topical in the modern technology of CZ crystals:

- Enlarging of the color range
- Increasing the size of crystals
- Increasing the optical perfection and uniformity of crystals for technical applications

A little later, in the middle of the 1970s, interest towards high-strength and high-viscosity materials based on ZrO_2 arose. One such material is partly stabilized zirconium dioxide (PSZ) – a solid solution of yttrium oxide or other rare-earth or alkaline-earth oxides in ZrO_2 . In 1975 the attention of researchers was concentrated on the creation of two-phase materials characterized by high destruction viscosity due to inherent phase transitions similar to martensitic transformations in steel. Thus, Harvey [14.63] obtained and extensively studied a material based on ZrO_2 partially stabilized by CaO. The new material was named *ceramic steel*. Ceramics of even higher characteristics were obtained when Y_2O_3 was used as a stabilizer and the tetragonal phase (TZP) was synthesized [14.64, 65]. The transformational mechanism of hardening was proposed in [14.66]. These results gave great impetus to the development of fundamental research on ZrO_2 -based material and studies on its synthesis and applications. An up-to-date review on the transformational mechanism of hardening of constructional ceramics is given in [14.67], where the theoretical aspects of transformational hardening are analyzed and experimental results on the microstructure and mechanical properties of ZrO_2 -based materials are presented.

Essential conditions for the preparation of high-strength high-viscosity construction ceramics are small grain size (10–100 nm) and that the residual porosity of the material be close to zero. Methods of non-porous ceramics preparation include high-temperature sintering, sintering under pressure, and hot pressing under isostatic conditions [14.68–70]. In order to obtain high-strength ceramics with high destruction viscosity by these methods one should use ultrafine (grain size ≈ 10 –200 nm) and highly homogeneous, uniform fused mixture. Nowadays much attention is paid to the preparation of ultrafine oxide particles as starting materials for the production of nonporous ceramics [14.71, 72]. The peculiarities of ceramic materials include randomness of the distribution of initial components, defects in the material structure (which may cause a significant scatter in material properties), and the presence of pronounced grain boundaries, which influence the properties of such materials significantly.

The SM method allows high-strength crack-resistant material with zero porosity without sharp grain boundaries to be obtained by directional crystallization of the melt. The possibility of synthesis under air, the lack of special requirements concerning grain composition and homogeneity of the initial materials, as well

as the practically waste-free character of the technology (i. e., the possibility of recycling crystalline waste) make this method very promising for the synthesis of these hard construction materials resistant to aggressive (in particular, oxidizing) gas atmosphere over a broad temperature range.

14.3.1 Crystal Structure of Zirconium Dioxide

Zirconium dioxide has several polymorphic modifications [14.73–75]. Monoclinic (m), tetragonal (t), and cubic (c) modifications of ZrO_2 exist at ambient pressure. The thermal stability range of the m-phase extends to 1160°C; that of the t-phase extends from 1160 to $\approx 2370^\circ\text{C}$; and that of the c-phase extends from $\approx 2370^\circ\text{C}$ to the melting point of ZrO_2 , $\approx 2680^\circ\text{C}$. Cubic phase of ZrO_2 is a nondistorted structure of the fluorite type, belonging to the $Fm\bar{3}m$ space group with lattice parameter $a = 5.07 \text{ \AA}$. The oxygen coordination number is 4, and the zirconium coordination number regarding oxygen positions is 8 [14.76, 77]. Tetragonal phase of ZrO_2 exhibits a slightly distorted fluorite structure, belonging to the $P4_2/nmc$ space group with lattice parameters $a = b = 5.085 \text{ \AA}$, $c = 5.166 \text{ \AA}$, and $a/c = 1.016$ [14.74–76]. The c-phase becomes unstable upon a decrease in temperature and is transformed to the t-modification by means of a small distortion of the fluorite structure. The symmetry of the initial structure is distorted as a result of small translocations of atoms, mainly of oxygen ions. Oxygen ions become shifted from their ideal positions (1/4, 1/4, 1/4) in the fluorite lattice but this does not lead to a change in the coordination number of zirconium. Four oxygen ions located at a distance of 2.065 \AA from each other occupy the apices of a tetrahedron; the other four ions occupy distorted tetrahedral positions and are located at a distance of 4.455 \AA from each other. On the whole, the lattice of the t-phase displays a minute elongation along the c -axis as compared with the lattice of the c-phase. Monoclinic phase of ZrO_2 belongs to the space group $P2_1/c$, with the following lattice parameters $a = 5.169 \text{ \AA}$, $b = 5.232 \text{ \AA}$, $c = 5.341 \text{ \AA}$, $\beta = 99^\circ 15'$, and $Z = 4$ [14.77–79]. The next phase transition, occurring at 1200°C , causes the transition from the t-form to the m-form. The latter form is stable under normal conditions, widely spread in the Earth's crust, and known as the mineral baddeleyite. Its structure is a result of further distortion of the c-phase of ZrO_2 , but the distortion is so pronounced that a completely new structural type emerges. The zirconium coordination number decreases from 8 to 7. Half of the oxygen atoms in the

baddeleyite structure are four-coordinated and the others are three-coordinated. It is important to emphasize that the structure of m- ZrO_2 is extremely stable, this being confirmed by the existence of m- ZrO_2 over a broad temperature range and the extreme stability of the mineral baddeleyite under natural conditions. Twinning is characteristic of the monoclinic structure. The twinning plane is constituted by oxygen ions – $\{100\}_m$ or $\{110\}_m$.

Pure $\alpha\text{-Y}_2\text{O}_3$ (cubic) has a volume-centered lattice and is isostructural to Mn_2O_3 . This structural type can be derived from the CaF_2 structure by deletion of a quarter of all nonmetallic atoms [14.80].

14.3.2 Phase Diagrams of the $\text{ZrO}_2\text{--Y}_2\text{O}_3$ System

Yttrium oxide is the most widely used stabilizing oxide for the growth of ZrO_2 -based crystals. That is why the $\text{ZrO}_2\text{--Y}_2\text{O}_3$ system will be extensively discussed in this chapter. The first phase diagram for the $\text{ZrO}_2\text{--YO}_{1.5}$ system was published in 1951 [14.81]. Many publications have appeared since then, but the experimental data obtained are often contradictory and the data for some parts of the phase diagram are not yet sufficiently reliable. The characteristic presence of wide solid-solution regions based on either ZrO_2 or Y_2O_3 was disclosed already during the first studies of the $\text{ZrO}_2\text{--Y}_2\text{O}_3$ system. The most reliable phase diagrams were plotted at the end of the 1970s [14.82–87] (Fig. 14.8).

These diagrams show that the ordered compound $\text{Zr}_3\text{Y}_4\text{O}_{12}$ formed at Y_2O_3 content of 40 mol % exists along with solid solutions. This compound was first synthesized and described in [14.82]. $\text{Zr}_3\text{Y}_4\text{O}_{12}$ displays a rhombohedral-type symmetry (space group $R\bar{3}$), is isostructural to UY_6O_{12} , and undergoes incongruent decomposition at $1523 \pm 50 \text{ K}$ [14.84], i. e., the structure is disordered to yield a fluorite phase.

Special attention was paid to the part of the phase diagram corresponding to zirconia-rich compositions because these materials are of great practical interest. A series of complicated phase transformations depending on the thermal history, grain size or particle size is observed in this part of the system. The presence of metastable states is common. A detailed analysis of these phase transformations is given in [14.88, 89]. A decrease in the temperature of the t–m phase transition accompanied by the increase in yttrium content is a characteristic property of this region of the phase diagram. A narrow two-phase (m–t) region exists in a range of temperatures above the temperatures to which the m-

Fig. 14.8a,b ZrO₂-Y₂O₃ phase diagrams: (a) after [14.82]; (b) after [14.83]

phase corresponds. This two-phase region is followed by the so-called transformable t-phase region. The t-phase, which is transformed into the m-phase upon cooling, exists in the composition range of 0–5 mol % YO_{1.5}. However, if the grain size of the ceramic sample is low enough (0.2–1 μm), the transformation of the material with YO_{1.5} content of 3–4 mol % into m-phase may not occur spontaneously at room temperature but takes place upon significant mechanical loading. The complexity and low rate of the m-t diffusion phase transition make the determination of equilibrium phase boundaries in the two-phase m+t region very difficult. Practically, the t ↔ m transition boundary was determined using various methods: differential thermal analysis, dilatometry, acoustic studies, and Raman spectroscopy. The data obtained in these studies were very incoherent, depending on the method of sample preparation, thermal history, presence and size of grains, purity of starting materials, etc. The samples were obtained by oxide mixtures sintering [14.87, 89] or by crystallization of the melt in a CC [14.90–92].

A two-phase region of untransformable tetragonal (t') and c solid solutions corresponds to higher YO_{1.5}

concentrations. Samples containing 4–13 mol % YO_{1.5} undergo a phase transformation into t'-ZrO₂ upon rapid cooling, starting from temperatures corresponding to the temperatures of existence of the c-ZrO₂ solid solution. This phase is named untransformable because it does not turn into the m-ZrO₂ phase. Upon an increase in yttrium oxide content the tetragonal distortion of the structure (*c/a*) decreases and its lattice parameters become very similar to the cubic parameters of the fluorite lattice. Such phase transitions in metallic systems are well known [14.93]. Their main features are the lack of changes of the chemical composition (the lack of diffusion) and a collective shifting of atoms during the transition (cooperative transformation). This transition is defined mainly by the rate of phase boundary migration. Various models of the phase transition process of this type were proposed, the choice of the model being determined by the temperature [14.94]. In the case of ZrO₂-YO_{1.5} the c ↔ t' transition occurs in the two-phase region c+t. The nature and properties of the t'-phase as well as its formation from the c-phase upon a phase transition are reviewed in detail in [14.95]. The boundaries of the two-phase region of c+t existence

Fig. 14.9a–c Phase diagrams for the $\text{ZrO}_2\text{--Y}_2\text{O}_3$ system calculated by CALPHAD [14.99]. Experimental data from: (○) [14.81], (+) [14.83], (×) [14.84], (●) [14.100], (Δ, □) [14.88], (*) [14.83], (◐) [14.101] dotted line: t–m transition temperature; dashed line: t–c transition temperature ►

were studied by many researchers [14.81, 84, 87, 95]. The use of various methods of sample synthesis and phase boundary determination causes a scattering of the values. For example, in the temperature range of 1823–2273 K the two-phase region t + c extends from 3–4 mol % to 10–13 mol % $\text{YO}_{1.5}$. Further increase of $\text{YO}_{1.5}$ concentration to 15 mol % $\text{YO}_{1.5}$ and above results in the formation of completely stabilized c solid solutions of fluorite type. The liquidus curves for the whole composition range were first plotted in [14.96]. Eutectic formation was detected at Y_2O_3 concentration of 87.1 mol % and temperature of 2643 K. Melting points of 2983 and 2712 K were determined for pure ZrO_2 and pure Y_2O_3 by the authors of this work. The calculation of phase diagrams (CALPHAD) method was used to give a complete description of the thermodynamic properties and equilibrium phase boundaries of the system $\text{ZrO}_2\text{--YO}_{1.5}$ [14.97–99]. The calculated phase diagram of the $\text{ZrO}_2\text{--Y}_2\text{O}_3$ system as well as separate fragments supplemented with points marking the experimental values is presented in Fig. 14.9.

14.3.3 Stabilization of Cubic and Tetragonal Structures in Zirconia-Based Materials

Stability in the whole temperature range including room temperature should be imparted to one of the high-temperature modifications of ZrO_2 in order to grow single crystals from the melt. The ratio of the cation (R_c) and anion (R_a) ionic radii was shown to be the critical parameter for fluorite lattice stability [14.102]. The face-centered anion package in the $Fm\bar{3}m$ lattice is possible if $R_c/R_a \geq 0.736$. If the parameter value is less than this value, the cubic structure cannot exist because forces of electrostatic repulsion inevitably distort the dense ion package when distances between the anions are small. For ZrO_2 this ratio is 0.66. The cubic lattice can be stabilized if the cation size is increased and the effective anion size is decreased. This may be achieved in two ways: by replacing the zirconium cation by a cation of a larger radius or by creating vacancies in the anionic sublattice (i. e., by introducing cations of lower charge). In order to achieve the required increase in the

ratio of the ion radii in the ZrO_2 lattice the lattice parameters should be increased by approximately 4%. In some cases stabilization is also achieved by introduction

of oxides with cations having a lower radius than that of the zirconium ion. Therefore, the cation radius is not a decisive factor for the formation of the ZrO_2 c-phase. The stable lattice is the one corresponding to the state of minimum free energy. Apart from the radii of the cation and anion, the character of the interaction between the electron shells of the lattice components is of a great significance for this state. References [14.103, 104] state that the bond between oxygen and the introduced cation must be more heteropolar than the bond between oxygen and the zirconium ion. In this case the fluorite structure is formed. The mechanism of stabilization of high-temperature modifications and the role of the oxygen vacancies formed upon heterovalent replacement of zirconium cations by lower-valency cations of the stabilizing oxide are discussed in several publications [14.105–107]. The degree of stabilization depends on the nature of the stabilizing oxide and its concentration. Oxides structurally similar to ZrO_2 are commonly used. According to crystallochemical conceptions, stable solid solutions can be formed in this case. Such oxides include Y_2O_3 , and oxides of rare-earth elements and alkaline-earth elements.

Tetragonal solid solution based on ZrO_2 can be obtained by decreasing the stabilizing oxide concentration. Single-phase samples with t-structure can be prepared only under strictly determined conditions [14.64, 65, 85, 108]. The stability of the t- ZrO_2 structure depends on factors such as density, composition, grain size, length of intergrain boundaries, and annealing conditions. As mentioned above, two forms of t- ZrO_2 exist [14.94, 100, 101, 109]: the t'- ZrO_2 , rich in Y_2O_3 , and the t- ZrO_2 , which is depleted of Y_2O_3 and can undergo a martensitic transition into the m-phase. The t'-phase is predominant in materials obtained by sharp quenching of c-solid solutions. Single crystals grown by directional crystallization of the ZrO_2 -3 mol % Y_2O_3 melt composition in a CC have a strongly twinned t-structure [14.110]. Cooling at a low rate facilitates the t \rightarrow m phase transition, i. e., the t-phase was not the t'-phase in spite of being richer in Y_2O_3 than the equilibrium t-phase. ZrO_2 -based ceramics with 2–9 mol % Y_2O_3 stabilizer, obtained by sintering, consists of two or three phases mainly. Monoclinic or t- ZrO_2 can be present in such materials in the form of coherent precipitates in a t- or c-matrix, according to the ratio of the crystallographic parameters of these phases.

The best conditions for preparation of samples consisting only of the t'-phase by directional crystallization of melt in a CC are Y_2O_3 concentration of

3 mol % and high cooling rate (> 400 K/h). These results are consistent with the experimental conditions determined in [14.111]. For the study of the t'-phase, crystals grown by SM were reheated up to 2150°C (stability region of the c-phase) for 10 min and then quickly cooled to room temperature (cooling time of 60 min) [14.112]. The c \rightarrow t transformation is accompanied by the formation of a domain structure in the crystals [14.109, 112, 113]. Orientation dispersion and the crystallographic correlations between domains are determined by both the prototype (c-phase) symmetry and the symmetry of the t'-phase formed from the c-phase. Domains form ordered colonies of two alternative variants separated by habitus planes $\{110\}$, which are the twinning planes. If the material contains only the t'-phase, then colonies occupy all of its volume, directly adjoining each other. They border on each other along the $\{110\}$ planes and are elongated along the $\langle 111 \rangle$ direction, forming a spiral-like structure. Detailed investigation of the domain structure of the t'-phase was performed in [14.112, 114–116]. It was found that tetragonal domains occupy all of the volume of t'- ZrO_2 . Their spatial arrangement must be highly symmetric in order to minimize the energy of coherent deformations [14.112]. Three-dimensional spatial arrangement of the colonies in pure t- ZrO_2 obviously differs from that in PSZ, where colonies of t-uniform domains are inserted into the uniform matrix [14.115, 117]. Colonies and their substructures are a result of the optimal accommodation of spontaneous stress caused by the c \rightarrow t transition. Upon a c \rightarrow t phase transition, the c-axis of the elementary cell is slightly elongated. In t'- ZrO_2 containing 3 mol % Y_2O_3 the elongation did not exceed 1%. This is approximately half that of the t-distortion for pure ZrO_2 with $c/a = 1.02$ [14.112]. Correspondingly, the domain c-axes are not orthogonal: the angle between them equals 89.4° in the case of a 1% distortion. It has been found that the domains inside the colony are separated by coherent low-energy twinning planes $\{110\}$.

14.3.4 Cubic Zirconia Crystals (Fianits)

As mentioned, the above-described SM method was most successfully applied for the development of an industrial technology for ZrO_2 -based single-crystal growth. Crystals up to 60 mm in length and up to 20 mm in cross section had been grown already at the beginning of the 1970s using the technology elaborated in Russia. Such crystals were obtained in the first industrial equipment including a CC of 180–200 mm in diameter.

The power of the RF generator was 60 kW, and the frequency was 5.28 MHz. The weight of the melt was up to 15–20 kg. Further development of the technology was aimed at achieving a larger size and higher quality of the crystals as well as at lowering their price. Using large melt volumes for crystal growth is the simplest and most efficient way of achieving these objectives because it allows:

- Growth of a much larger quantity of crystals during one crystallization cycle at the same crystallization rate. This allows lowering of the production costs.
- Lowering the heat losses through the walls of a CC and the corresponding lowering of the RF generator input power; the ratio of cooled surface area to the melt volume is much less in larger CC.
- Improving the crystallization conditions in order to obtain high-quality crystals. When the melt volume is large, the system has a high thermal inertia which levels out random oscillations of RF output power on the crystallization front.
- Preventing the formation of cracks in large crystals during the cooling of the crystalline ingot. At large melt volumes the cooling rate of the crystals after complete of the crystallization is much lower.

This was confirmed with experience on industrial equipment with a CC of 400 mm in diameter, output power of 160 kW, and RF frequency of 1.76 MHz. The weight of the melt was 80–100 kg. Nowadays large-scale production of single crystals is mainly performed in facilities with CC diameter up to 1000 mm, power of 800 kW, and frequency of 400–800 kHz. The weight of the melt is 600–1500 kg. The weight of individual crystals reaches 15 kg.

Growth of CZ Crystals

The scheme of manufacturing of CZ crystals is shown in Fig. 14.10. The main technological stages are the following: preparation of the initial mixture, loading of the initial mixture into the CC, SM of the material, directional crystallization of the melt, extraction and separation of the crystal ingot, crystal cutting and sorting, and processing of the material and offcuts. The most important stages of the technological process will be discussed below.

The oxides used as starting material are weighed and thoroughly mixed in a ratio corresponding to the predetermined concentration. In the case of mass production, various quantities of crystalline melted material of the same composition from previous melts are

added to the initial mixture [14.25, 30, 118]. ZrO_2 and Y_2O_3 are the main raw materials, their purity being of great significance for the crystallization conditions and the degree of structural perfection of the crystals. The presence of some trace contaminants in the oxides used for crystal growth by directional crystallization in the CC is highly undesirable. These contaminants influence both the growth process and the quality of the single crystals obtained. Atomic emission spectroscopy studies have shown that the concentration of contaminants in the crystals obtained is 5–100 times less than that in the starting oxides due to the evaporation of the volatile oxides (namely, oxides of As, Pb, Cu, etc.) and the segregation of impurities (Si, Ti, Al, W, etc.) during directional crystallization [14.25, 30] (Table 14.2).

Requirements concerning the purity of the starting materials depend on the field of application of the crystals. For example, the content of Si, Ti, Al, and W in oxides used to synthesize crystals of high optical uniformity and structural perfection for optical applications must not exceed 10^{-4} – 10^{-5} wt %.

Putting the initial materials into the CC is an important technological stage that greatly influences the reproducibility and crystal yield in the cycle, as well as the size and quality of crystals. The method of loading influences the processes of start melting, the formation of the melt volume, and the thermal conditions under which further melting and subsequent crystallization of the melt proceed. As already mentioned, thermal shielding of the melt plays an important role during SM in a CC. The lower thermal shield is formed during crucible loading. As a rule, crystalline melted pieces of the previous processes and the initial powders of the same composition are used to form the shield. The position of the shield is determined experimentally to create appropriate thermal conditions for crystallization. If large quantities of crystalline material are used, circular loading of the CC is often performed [14.118]. Circular loading ensures the formation of a dense, reliable sintered skull. Thus heat losses are decreased and leakage of the melt from the CC through intersection gaps is prevented. As a result, the stability of the melting process becomes higher. In the case of a large-diameter CC this loading method ensures reproducibility of the start melting process and creates the optimal conditions for the formation of large melt volumes required for obtaining large crystals at the lowest power values possible.

During the melting of the initial charge the molten zone approaches the CC walls; emission of radiation through the intersection gaps situated in the upper part of the charge begins and gradually becomes more in-

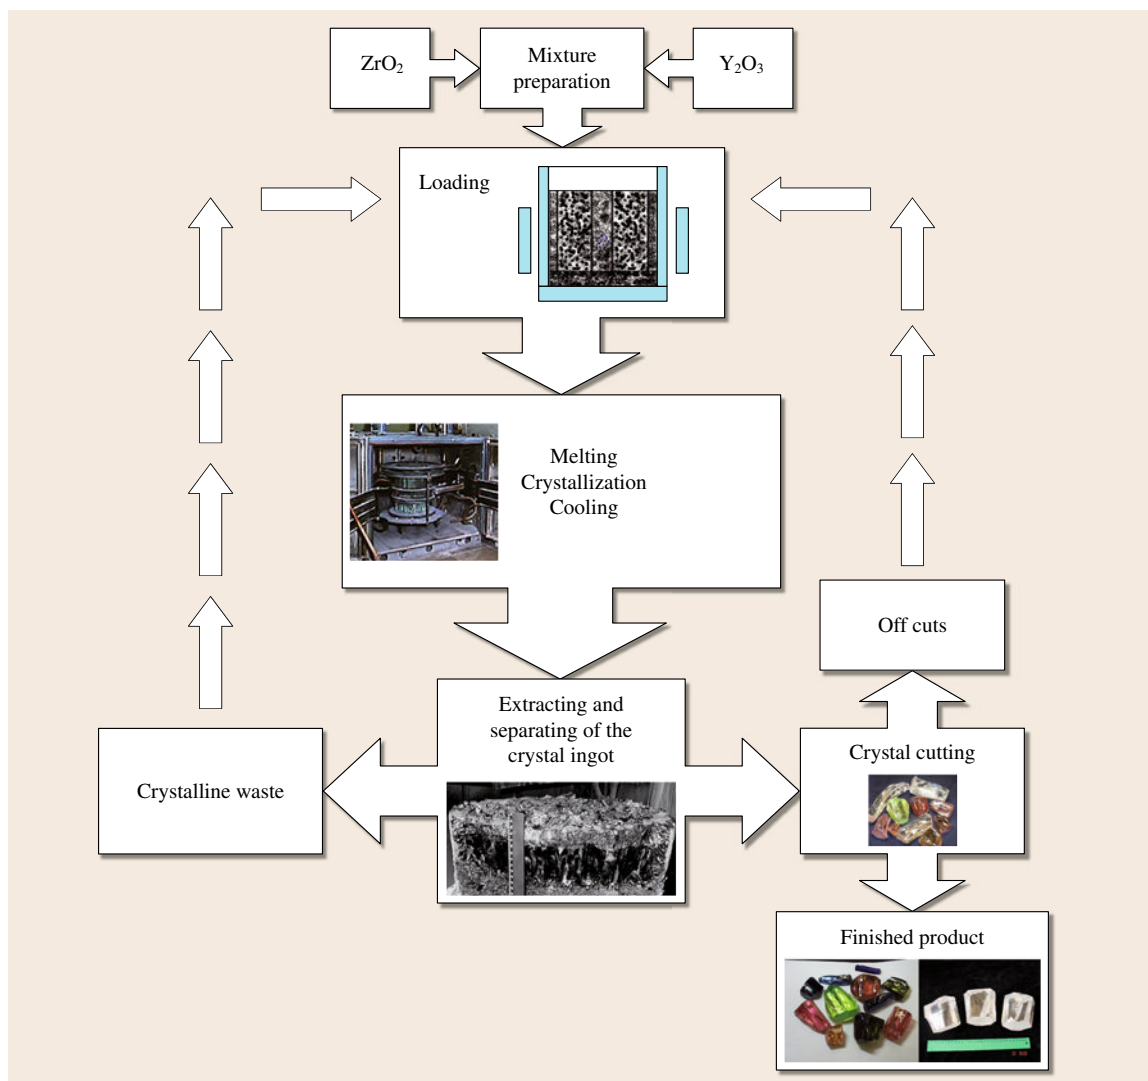

Fig. 14.10 Process flowsheet of the production of crystals based on zirconia

tense. The importance of providing an upper shield for the melt upon crystal growing by directional crystallization from the melt in large CCs was mentioned above. Choice of the size of the upper thermal shield and the method of its formation vary depending on the method of melt volume formation during start melting. If portions of the initial powders are not added during melt volume formation, then the remaining sintered arch of powdered material acts as a heat shield. If initial powders are added during the process of melt formation, then crystalline material (of the same composition) of previous processes can be used for shield formation.

This material is loaded after the completion of melt formation. This material does not melt because it remains above the RF coil level during loading; only partial melting of the lower part of the shield may occur. Studies on the initial melt volume formation in the CC have shown [14.33–36] that the same volume can be formed in different ways (Fig. 14.11).

The character of melting depends on the characteristics of the starting material. Studies were carried out for ZrO_2 powders of different dispersity. The experimental data showed that more power is needed for the melting of a less porous (porosity ε_1) powder than for a more

porous one (porosity ε_2). Properties of the initial material (in particular the powder porosity) determine the direction of the melt spreading during the stage of start melting, as well as the structure of the skull. It was confirmed that two modes of melting of a porous dielectric exist: the stationary mode and the quasiperiodic mode. The mode observed is determined by the ratio of the threshold power density (depending on the porosity of the initial powder) and the density of power released in the charge. This experimental data confirmed the theoretical model of induction melting of dielectrics proposed in [14.119]. It was shown that the direction of melt spreading during the initial stage of melting influences the volume and the shape of the molten bath

formed, the value of power released in the melt, the value of melt overheating, and the power of heat losses in the charge. The preferable variant of spreading during melting is spreading towards the bottom of the CC. In this case less power is needed for the molten bath formation, the melt overheating is less pronounced, and the melting process is more stable without leakage of melt through the gap between the sections. The mode of initial melt formation is especially important when large CC or charges of large mass are used, or when power is limited. The use of the above-mentioned circular loading method considers the advantages of melt volume formation by spreading of the melt towards the bottom of the CC and thus promotes the formation of large melt

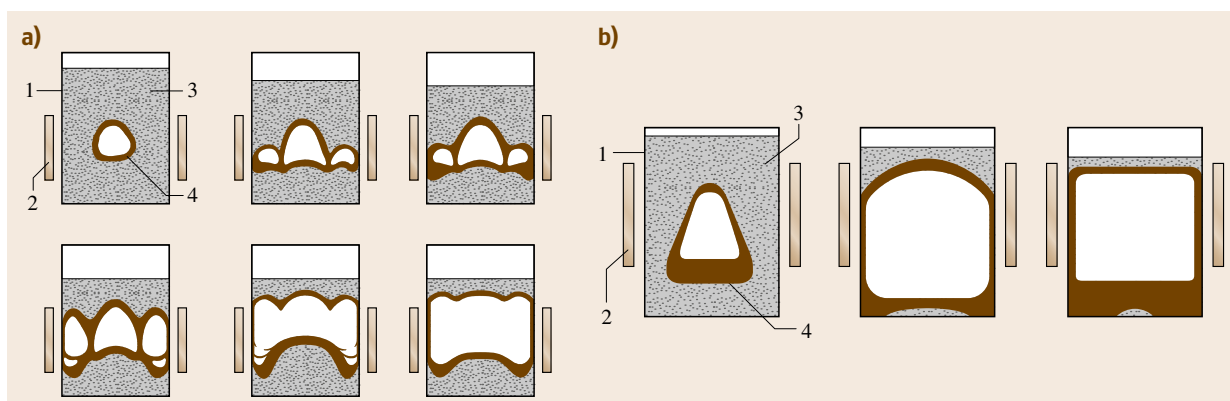

Fig. 14.11a,b Schematic of the melt propagation at melting initial powder with different particle size ε_1 (a) and ε_2 (b). 1 – Cold crucible; 2 – induction coil; 3 – powder of initial materials; 4 – melt

volumes at minimal power values. After the end of melting, the melt is homogenized to achieve thermal and phase equilibrium.

Crystallization of the melt begins on the bottom of the CC on crystal grains of the solid skull. Only a restricted number of crystals of those initially formed remain during growth. As a result of crystallization, a columnar block of single crystals grows. The size of CZ crystals grown by SM technique is influenced by:

- The conditions of formation of the initial melt volume determining the temperature gradients on the interface, which influence the geometry of the crystallization front and the position of this front relative to the heating zone
- The conditions of nucleation on the skull
- The conditions of degeneration during mass crystallization
- The chemical composition of the initial melt (the nature and concentration of the stabilizing oxide and the presence of impurities)

The melt–solid interface geometry may be concave, flat or convex depending on the conditions of the melt volume formation. The last two types are preferable for crystal growth in the CC as well as for traditional directional crystallization in hot crucibles because they promote a decrease in the number of growing crystals and a consequent increase of crystal size; they also ensure low thermal strains and high purity of the growing crystal. The experience of growing CZ crystals by SM technique shows that larger crystals are formed when the crystallization front is flat or convex, other conditions being equal. In the case of a concave crystal-

lization front the number of crystals formed increases, while their size, especially the size of the crystals in the central part of the ingot, decreases (Fig. 14.12). The actual crystallization front may have a more complex shape and change its geometry during crystallization corresponding to changes in thermal conditions.

Nucleation. The nucleation process determines the size and quantity of growing crystals. Authors [14.120] have described the peculiarities of SM of porous dielectrics during the stage of melting wave propagation, when capillary spreading of the melt takes place inside the pores of the dielectric powder. During this process the melt impregnates the solid phase and crystallizes in it, then slow melting of the crystallized layer takes place, and then the situation cycles. These processes of capillary spreading determine the local structure of the interface on which the single-crystal growth begins. The melt from the heated zone causes partial melting of the upper layer of the lower thermal shield. This layer being nonuniform and porous, the melt penetrates into the surface layer nonuniformly. The photograph of the fragment of the lower part of a crystal (Fig. 14.13) clearly shows that inclusions of unmolten initial powder and bubbles are present in the crystal.

The Laue pattern of this part of the crystal indicated that the atomic planes are heavily distorted near the inclusions but the crystal structure remains single-crystalline. Nonuniformity of the nucleation interface leads to the formation of a great number of crystals and thus decreases the cross-sectional size of isolated crystal. So, the lower thermal shield influences the nucleation process greatly. When this shield is lacking, the thin skull is substantially nonuniform due to the random

Fig. 14.13 Section of the bottom part of the crystal

character of heat removal in different regions (even direct contact of the melt with the bottom of the CC is possible). This nonuniformity is significantly decreased if a dense heat-insulating layer is formed. This causes a significant decrease in the number of seeded crystals and the increase of the size of crystals already at the nucleation stage. Besides, such a shield allows the use of seeds placed on it. Unfortunately, this seeding process is uncontrolled, has a random character, and requires experimental selection of conditions to increase its repeatability. Nevertheless, crystals were grown on seeds of different orientations [(100), (111), and (101)] and X-ray studies showed that the crystals inherited the crystallographic orientation of the seeds.

Degeneration. The degeneration process consists of a decrease in the number of seeding crystals and is accompanied by an increase in the cross-sectional size of some crystals at the expense of a decrease in the size of other crystals. The problems of competitive growth were analyzed in studies of mass crystallization [14.121–125]; the selection of crystals according to their size was shown to be a result of these processes and so-called *geometric selection*. The mechanism of this process is the following: crystals survive the competition only if their direction of fastest growth is close to the normal of the nucleation surface. As a result, all crystals separated from the nucleation surface by a distance greatly exceeding the mean distance between the nuclei are elongated and their geometric axes are almost parallel to each other: the so-called columnar structure occurs. The formation of such a structure is influenced by only geometric factors, the influence of external conditions (for example, the direction of heat transfer from the growing crystal) being small. It was supposed that the influence of external factors could be only indirect and result in a change of facet growth rate and

crystal habitus. Quantitative experiments on geometric selection [14.126, 127] showed that the linear density of the number of surviving crystals $n(h)$ decreases proportionally to the height $n \sim 1/h$. The probabilistic assessment [14.128] yielded the same result for the two-dimensional case and a dependence expressed by the formula $n \sim 1/\sqrt{h}$ for the three-dimensional case. The aspect ratio depends on the crystal habitus in both cases.

A theory of crystal degeneration based on studies of the mass crystallization of metals with a face-centered lattice was proposed by Tiller [14.123–125]. It was supposed that grooves formed by boundary surfaces of crystals exist on the interfaces of growing crystals. The depth of the grooves was supposed to depend on the temperature gradients in the solid phase and the melt, as well as on the orientation of the neighboring crystals. The inclination of groove slopes is determined by crystal orientation. Thus a crystal with $\langle 111 \rangle$ orientation relative to the growth axis has a greater slope inclination than a crystal with $\langle hkl \rangle$ orientation, so it will hang over the latter crystal and finally displace it. Such grooves were observed upon growing CZ crystals [14.129]. It was noted that, upon consideration of the degradation process in the framework of Tiller's theory, a decrease of the heat power released in the melt causes a decrease of the mean temperature of the melt and a corresponding decrease of axial gradients at the crystallization front. The decrease in the gradient causes an increase in the depth of the groove between the growing crystals and makes the degeneration process more efficient.

The melt volume influences the size of CZ crystals: larger crystals can be grown in large-volume CCs, exceeding 200 mm in diameter [14.25, 30, 118]. In the case of small crucibles (90–100 mm) the high ratio of the cooling surface area to the melt volume and high heat losses through the CC walls require a higher melt overheating. Significant melt overheating deleteriously influences the degeneration conditions and the shape of the crystallization front [14.129]. The growth rate influences the degeneration process of CZ crystals in the following way: a decrease in the growing rate leads to an increase in the crystal size [14.30, 118]. This corresponds to Tiller's theory of degeneration, which states that the ratio of the rate of displacement of the competing nuclei to the axial growth rate is higher when the growth rates are lower and thus the displacement process becomes more efficient. The influence of melt composition (in particular, the nature and concentration of the stabilizing oxide) on the crystal size was stud-

Fig. 14.14 Mean size of $\text{ZrO}_2\text{-Y}_2\text{O}_3$ crystals versus Y_2O_3 concentration and growth rate

ied in [14.25, 30]. The dependence of the *mean size* of the crystals obtained at different crystallization rates (3, 10, and 20 mm/h) in a CC of 130 mm diameter on the Y_2O_3 concentration is shown in Fig. 14.14. The *mean size* $d = D/n$, where D is the diameter of the ingot and n is the number of crystals in ingot cross-section, was used to compare crystals from different ingots.

The growth conditions were selected for the crystallization front to remain flat throughout the process and for the melt height to be approximately the same for different compositions (the melt height was about ≈ 50 mm, thus being less than the crucible diameter, and this diminished the influence of the degeneration processes). Figure 14.14 demonstrates that an increase in Y_2O_3 concentration (especially above 20 mol %) causes a decrease in the *mean size* of crystals. Consequently, the growth rate must be significantly decreased to maintain an acceptable size of crystals at high Y_2O_3 concentrations.

As mentioned before, impurities that influence the growth of crystals are present in the starting materials. Besides, large quantities of additives may be introduced into the crystals to vary the physicochemical properties of crystals (optical, spectral, electrical, mechanical, and others). These additives significantly influence the crystallization process and, consequently, the size of crystals. It is well known that directional crystallization of multicomponent melts with component distribution coefficients (K) not equal to 1 is accompanied by segregation of the component decreasing the crystallization temperature, into the melt, and its accumulation at the crystallization front (if $K < 1$). In Tiller's theory, grooves on crystal interfaces act as sinks for such ad-

mixtures. Thus, the segregation of admixtures inhibits the lateral growth of crystals, and causes an increase in the groove depth and retardation (or complete stop) of the degeneration process. Therefore the introduction of additives, as well as the use of initial mixture with high levels of impurities requires correction of the growing conditions.

Many studies of mass crystallization of metals have been devoted to the problem of preferential orientation of grains in the ingots [14.121–123]. The growth rates anisotropy attempted to give an explanation of the preferential orientation of grains in the ingots: the anisotropy was believed to be due to the anisotropy of the heat conductivity in the crystal. Higher heat conductivity in the temperature gradient direction was suggested to be the cause of the difference in the grain growth rates. However, this is possible only for crystals characterized by anisotropy of heat conductivity, whereas heat conductivity anisotropy is known to be low for most crystals and to be zero for cubic crystals. Experiments on bicrystal growth showed that the equilibrium temperature of the crystal contacting the melt depends on the crystallographic orientation relative to the interface. Dependence of the preferential crystallographic orientation on the growth rate, value of overcooling, and presence of admixtures in the starting material was also noted in these experiments. The problem of preferential crystallographic orientation of CZ crystals grown by SM technique has not been studied in detail. The preferential crystallographic orientation of CZ crystals was shown to be $\langle 110 \rangle$ [14.13, 25, 31, 130, 131]. However, experience shows that the deviation of the crystal growth axis from this direction may often amount to tens of degrees. The correlation structure and morphology of CZ crystals was studied in [14.132]. Single crystals of $\text{M}_x\text{Zr}_{1-x}\text{O}_{2-x/2}$ ($\text{M} = \text{Y}, \text{Er}, \text{Yb}$) with $0.3 < x < 0.57$, i.e., crystals with high stabilizer content, were studied. In accordance with the phase diagram, formation of the ordered compound $\text{Zr}_3\text{Y}_4\text{O}_{12}$ was observed at $x = 0.4$. The phenomenon of short-range order was shown to influence the crystal morphology significantly. The interpretation of results was based on the analysis of structural characteristics of ordered rhombohedral phases of the type Y_6UO_{12} by the method of Hartman and Perdok [14.133]. This method supposes the crystal habitus to be determined by chains of strong bonds. This work clearly demonstrates how the lattice symmetry, the nature of the solid solution, and the crystal growth conditions influence the shape of CZ crystals.

Properties of CZ Crystals

CZ crystals grown by **SM** technique have been studied rather extensively with regard to chemical and phase compositions, determination of the range of stabilizer concentrations allowing preparation of cubic solid solution crystals from the melt, determination of the phase stability of the crystals, and characterization of growth defects [14.25, 28–31, 61, 134–140]. The structure of crystals was studied in detail by X-ray analysis, Raman spectroscopy, electron paramagnetic resonance, neutron diffraction, etc. [14.91, 113, 141–146]. Lattice parameters and the mechanism of cubic solid solution stabilization were also studied [14.144–149]. A number of investigations have been devoted to the physico-chemical properties of crystals: electrical and optical properties [14.150–154], spectral generation characteristics of the activated crystals [14.155–163], and thermophysical and mechanical properties [14.164–177]. Studies of these properties of crystals are of a great significance for practical applications. It should be mentioned that the possibility of using crystals for different applications is to a great extent determined by the perfection of crystals. Therefore types of imperfections appearing in **CZ** crystals as well as causes of the appearance of imperfections and possible ways of their elimination will be discussed in the following section.

Defects in CZ Crystals

Growth striations, cellular structure, and inclusions of extrinsic phases are imperfections characteristic of **CZ** crystals [14.28, 29, 138, 139] (Fig. 14.15a–h).

Growth striations. Growth striations are observed in crystals of various compositions as layers with different refraction indices. They appeared as alternating layers perpendicular to the direction of growth of the crystals (Fig. 14.15a). Appearance of striations in $\text{ZrO}_2\text{--R}_2\text{O}_3$ crystals is indicative of nonuniformity of the components distribution during the crystallization process, in particular of nonuniform distribution of the stabilizing oxide. Local concentration measurements showed that Y_2O_3 concentration fluctuations do not exceed 1 mol %. Such factors as the stabilizing oxide concentration, crystal growth rate, and nature of melt stirring were found to influence the striae density [14.25, 28, 29]. A considerable increase in the density of the striations was observed at concentrations close to 30 mol % R_2O_3 , as well as upon an increase in lowering rate above 16 mm/h. When the lowering rate was decreased from 16 to 1 mm/h (for $\text{ZrO}_2\text{--}8\text{--}20$ mol % R_2O_3 compositions and **CC** of 90–200 mm in diameter), the striae

density decreased from ≈ 20 to $\approx 8\text{ cm}^{-1}$. When forced stirring by reverse rotation of the crucible was used at low lowering rates, striae density decreased and reached 1 cm^{-1} . As is known, nonuniform impurity distributions in crystals is caused by irregular growth rate, resulting in corresponding changes of the effective distribution coefficient and impurity concentration. Growth rate changes may be caused either by peculiarities of the instrumentation or by the processes taking place at the crystallization front. Striations caused by factors of the first type are usually called instrumental while those caused by factors of the second type are called fundamental. Under real conditions, factors of both type usually act simultaneously.

Instrumental striations may be caused by shortcomings of the crystal growth equipment (unstable functioning of the mechanical drives and **RF** generator output power, oscillations of the coolant flow, etc.) and also by changes of the growth rate caused by temperature oscillations in the melt due to convection. A study of the causes of growth striation formation [14.28, 29] showed that striations are caused by oscillations of the stabilizing oxide concentration (these oscillations are due to constitutional supercooling during growth) and can be eliminated by decreasing the lowering rate to 1–2 mm/h and introducing forced stirring by reverse rotation of the crucible with the melt. It was shown that instrumental instability can cause striations in this case, but this is not the main cause of striations. More uniform crystals are formed upon an increase of the melt volume. Increase of the melt volume causes an increase in the thermal inertia of the crystallization system. High thermal inertia significantly reduces the influence of oscillations of the power supplied by the **RF** generator and removed by water from a **CC**, i. e., suppresses the temperature fluctuations, maintaining the stationary state in the system. This results in stabilization of the crystallization front and increases the homogeneity of crystals. This situation was observed upon growing **CZ** crystals from a **CC** of more than 400 mm in diameter when the density of the growth striations decreased to $1\text{--}2\text{ cm}^{-1}$ upon decreasing the rate to 2–3 mm/h without forced stirring. The determination of the K of components of solid solution in ZrO_2 is very important for growing homogeneous **CZ** crystals.

Distribution Coefficients of the Solid Solution Components

The K of a component denotes the ratio of concentrations of this component in a liquid and solid phase having a common interface. Actually one usually deals

Fig. 14.15a–h Defects in cubic zirconia single crystals: (a) growth striae; (b) cellular structure; (c) growth striae and cellular structure; (d) light scattering of laser beam in the crystal; (e) light scattering in the defect area; (f) inclusions in the boundaries of cells; (g) inclusions containing SiO_2 ; (h) SiO_2 inclusions on the surface of ZrO_2 –10 mol % Y_2O_3 crystals

with effective distribution coefficients (K_{eff}) which differ from the equilibrium coefficients (K_0). K_0 characterizes the ratio of concentrations corresponding to the solidus and liquidus curves of the phase diagram having a common node. The directional crystalliza-

tion processes take place with finite rate, so greater or lesser deviations from equilibrium occur. To determine the value of K_{eff} , the distribution of the components along with the axis of the crystal is measured. Quantitative element analysis was performed by electron probe

Fig. 14.16 Distribution of Y_2O_3 concentration in ZrO_2 - Y_2O_3 crystals of different compositions. Initial composition (mol.% Y_2O_3): (▲) – 35; (□) – 15; (◆) – 7.5

microanalysis [14.25, 28, 30, 31] or by optical spectroscopy [14.134, 135]. The experimental results were approximated by the equation $C(g) = kC_0(1 - g)^{k-1}$, which is commonly used to describe the processes of normal directional crystallization [14.25, 28, 30, 31]. An example of measurements of the stabilizing oxide concentrations in ZrO_2 - Y_2O_3 crystals of different composition is given in Fig. 14.16.

A more detailed study of the Y_2O_3 distribution curves in crystals taken from different parts of the ingot showed that periodic nonuniformity of crystal composition along the growth direction occurs, resulting from oscillations of the crystal growth rate [14.28]. Waves in concentration curves of crystals taken from different parts of the ingot did not coincide, this being indicative of differences in crystallization conditions along the ingot cross-section (the crystallization front not being flat). Sometimes sudden changes of concentration were observed in the distribution curves. Such changes can occur due to an abrupt change of power supplied by a RF generator, causing a dramatic change of the crystallization rate, or to quick uncontrolled growth caused by constitutional supercooling. As a rule, such sharp concentration changes took place at the end of crystal growth. This is due to accumulation of the displaced admixtures in the melt and enhancement of the constitutional supercooling, which disturb the stable growth of crystals, causing the formation of inclusions and cellular structure. Besides, the coupling between the RF field and the melt is deteriorated when the amount of melt decreases, and this results in quick uncontrolled crystallization of the remaining melt. Changing the lowering rate of a CC in the range of 1–16 mm/h and changing the concentration of the stabilizing oxide weakly influenced the character of the distribution curves. The

values of K_{eff} for different growth rates and compositions are presented in Table 14.3. The values of K_{eff} of Y_2O_3 calculated from these data are close to 1 and only slightly depend on the growth rate and initial concentration of Y_2O_3 .

The values of K_{eff} for Gd – Yb oxides are close to those of Y_2O_3 in cubic solid solutions based on ZrO_2 and also slightly depend on the growth rate and initial concentration of stabilizing oxide [14.25, 30]. The values of K_{eff} for rare-earth oxides from the left part of the lanthanide series (Ce–Nd) in cubic solid solutions based on ZrO_2 were found to be less than 1 [14.25] (Table 14.4).

Data on the dependence of K_{eff} in CZ crystals with 12 mol % Y_2O_3 doped with 1.2265 wt % Nd_2O_3 on growth rate are shown in Table 14.5 [14.134]. Using the data obtained, the authors determined that, for Nd_2O_3 , $K_0 = 0.426$ and the diffusion layer is approximately 1 mm thick.

Cellular structure [14.25, 28–31] was observed in crystals extracted from the central part of the ingot and, as a rule, in the top part of the crystals (Fig. 14.15b). The top of the crystals exhibiting cellular structure had a characteristic *rudded* appearance; if the cellular structure was highly developed, boundaries between smooth shiny surface and uneven wavy surface could be clearly seen on the sides of the crystals. Regions exhibiting lamellar and cellular structure can alternate in the same crystal (Fig. 14.15c). The appearance of cellular structure is accompanied by a decrease in the striae density. The formation of cellular structure is caused by the destabilization of the smooth crystallization front upon growing [14.178–180]. Most authors consider constitutional supercooling of the melt near the phase interface to be the cause of destabilization of the smooth front and its transformation into the cellu-

Table 14.4 Effective distribution coefficients of Nd₂O₃ and CeO₂ in the ZrO₂-0Y₂O₃-Nd₂O₃-CeO₂ system

Composition	V (mm/h)	<i>K</i> _{eff} Nd ₂ O ₃	CeO ₂	Y ₂ O ₃
ZrO ₂ -(12-25 mol %) Y ₂ O ₃ -(0.74-4.40 mol %) Nd ₂ O ₃	5	0.62 ± 0.04	–	1.045 ± 0.03
ZrO ₂ -(9-11 mol %) Y ₂ O ₃ -(2-2.5 mol %) Nd ₂ O ₃ -1 mol % CeO ₂	5	0.58 ± 0.08	0.42 ± 0.04	1.09 ± 0.02
ZrO ₂ -3 mol % Y ₂ O ₃ -0.3 mol % Nd ₂ O ₃ -0.4 mol % CeO ₂	10	0.87 ± 0.08	0.78 ± 0.02	1.13 ± 0.01

lar type [14.180]. Constitutional supercooling alone was shown to be insufficient for the formation of cellular structure; a threshold value of constitutional supercooling depending on the chemical composition of the melt and the direction of growth had to be achieved. Studies of CZ crystals [14.25, 28–31] showed that the cellular structure appears at the end of the growth stage, most often in crystals situated in the central part of the crystalline ingot. This is connected both with the accumulation of admixtures in the melt before the crystallization front during crystal growth and with the character of the temperature distribution in the CC. Cellular structure, appearing as a *constriction* in the middle of the crystal, was formed at high growth rates (> 10 mm/h) in the absence of stirring.

Oxides of Si, Al, Ti, and W cause the appearance of imperfections deleterious to the optical uniformity of the crystals. Of all the contaminants mentioned, SiO₂ exerts the most negative influence on the growth and perfection of crystals. Even small quantities of SiO₂ promote disruptions of crystal growth and the appearance of cellular structure regions. Decreasing the growth rate and using forced stirring improves the efficiency of impurity segregation and the crystal quality [14.25, 28–30].

Inclusions [14.25, 29–31]. Large isolated inclusions and bubbles are seldom observed in CZ crystals; inclusions formed by light-diffusing particles of 10–0.08 μm in size are observed much more often. Light scattering can be observed either visually or by the scattering of a laser beam passing through the crystal (Fig. 14.15d). The occurrence of light-scattering regions depends on the composition of the melt and the growth conditions. Single crystals may be completely opalescent or exhibit broad opalescent bands in the top central part of the ingot (Fig. 14.15e). Research [14.25, 29–31] showed that band-shaped light-scattering regions coincide with regions of cellular growth. It was established that light-scattering inclusions may be formed during melt crystallization in CZ crystals either on all the phase interface or on the boundaries of the cellular structure (Fig. 14.15f,g). Growth of CZ crystals in a wide range of concentration of the stabilizing oxide at growth

rates of 1–2 mm/h showed that light scattering by the whole crystals is characteristic of compositions with 8–12 mol % R₂O₃ (R = Y, Gd) [14.25]. X-ray diffraction patterns of these crystals were not indicative of the appearance of new phases. Scattering in these crystals was caused by particles of the second phase with size of 1–0.1 μm. Under the same growth conditions, increasing the concentration of the stabilizing oxide to above 14 mol % R₂O₃ (R = Y, Yb) or above 16 mol % Gd₂O₃ completely eliminated light scattering in the crystals. The appearance of light-scattering particles may be connected either with the presence of impurities becoming less soluble upon a decrease in temperature (in this case it depends on the melt composition) or with the decomposition of the fluorite-type solid solution. Low concentration of the second phase and the very small size of its particles complicates direct determination of the phase structure and composition. It is worth mentioning that heat treatment of ZrO₂-12 mol % Y₂O₃ crystals at 2100 °C for 3 h under vacuum and subsequent quenching (at cooling rate of 1000 °C/h) led to elimination of light scattering. Large inclusions of the second phase (> 0.5 μm) are an extreme case of inhomogeneity of the crystal and are usually located in regions of highly developed cellular structure. As a rule, such inclusions are caused by the presence of unde-

sirable impurities in the initial mixture. The type of inhomogeneity caused by the presence of admixtures is determined by the nature and concentration of the admixture (SiO_2 , TiO_2 , Al_2O_3 , WO_3). Large (4–10 μm in size) silicon-containing inclusions of the second phase were detected in the boundaries of cells (Fig. 14.15f,g). The density of such inclusions in the top part of the crystal varies from 4.5×10^2 to $26 \times 10^2 \text{ mm}^{-3}$.

Electron probe microanalysis of the inclusion composition showed that the concentration of SiO_2 in the inclusions is very high ($\approx 60 \text{ mol } \%$). The spherical shape of such inclusions and their compositional nonuniformity suggest that trapping of the liquid phase occurs. The melting point of the SiO_2 -enriched drops being lower than that of $\text{ZrO}_2\text{--R}_2\text{O}_3$, these liquid drops become trapped in the solid crystal matrix. The concentration of Y_2O_3 in the inclusions is also higher than in the matrix because R_2O_3 , being oxides of basic character, accumulate in the drops due to chemical affinity towards SiO_2 , which is more acidic than ZrO_2 . The process of chemical differentiation takes place either upon drop formation or upon drop cooling (in the latter case it is due to diffusion from the solid matrix). High content of stabilizing oxide in the inclusions (up to 28 mol % in the case of $\text{ZrO}_2\text{--}12 \text{ mol } \% \text{ Y}_2\text{O}_3$) may cause decomposition of the cubic solid solutions and formation of m-ZrO_2 if the concentration of SiO_2 is sufficiently high and the concentration of the stabilizing oxide is low. However, the probability of this process is low if the Y_2O_3 concentration in the cubic crystals is high. Apart from forming inclusions inside the crystal, the second phase can form precipitates on the surface of blocks (Fig. 14.15h). In this case a matted deposit appears on some parts of the crystal facets, which is usually smooth and very shiny [14.25, 29–31].

14.3.5 Growth, Properties, and Application of PSZ Crystals

The SM technology of PSZ crystals is similar to the above-described growth process of CZ crystals. The growing PSZ crystal exhibits a c-structure during the first stage of synthesis from melt; phase transitions in the crystal occur upon cooling of the solid phase. The $\text{c} \rightarrow \text{t}$ phase transformation is accompanied by the formation of domain structure in the crystals [14.130–132]. PSZ crystals are used mainly for scientific research on the mechanism of hardening, structural, micro- and nanostructural research, studies on phase transformations, and physicochemical properties [14.109, 112, 116, 149, 181–183]. Although the advantages in mechan-

ical properties (high hardness, strength, and fracture toughness) of PSZ crystals, especially at elevated temperatures, have apparently been demonstrated, practical applications of PSZ as construction material have not yet been reflected in the literature.

Large uniform blocks of material without cracks are required for practical applications. This is why the influence of composition and growth conditions on the size and mechanical properties of crystals was investigated [14.184–187]. The stabilizing oxide concentration range (2.5–4 mol % Y_2O_3) allowing the preparation of large (up to 40 mm in cross-section, up to 120 mm in length) uniform PSZ crystals not containing fractures has been established [14.188]. PSZ crystals of the composition $\text{ZrO}_2\text{--}2.5\text{--}4 \text{ mol } \% \text{ Y}_2\text{O}_3$ are white and nontransparent, with a smooth shiny surface. The crystal surface becomes rough and matted upon a decrease in Y_2O_3 content. The crystal size is significantly decreased at Y_2O_3 concentration $< 1 \text{ mol } \%$. Crystals containing 5–8 mol % Y_2O_3 are semitransparent and contain a large number of fractures in the volume. Experiments on the growth of crystals in a CC of 130 mm diameter showed that rate decrease from 40 to 3 mm/h led to a significant increase in the crystal cross-section size (from 3–7 mm to 20–40 mm) [14.185, 186] (Fig. 14.17).

However, growing the crystals at 3 mm/h rate results in a considerable increase in the number of fractures in the crystals. The cooling rate in the crucible of 130 mm diameter being too high for crystals of a large size, residual thermal stresses are probably relieved by means of fracture formation in the crystals. Research into the influence of thermal conditions on crystal growth showed that the quantity of large cross-section crystals is significantly increased upon an increase of the height of the bottom thermal shield. Most crystals have a smooth shiny surface.

Fig. 14.17 PSZ crystals grown at 3, 20, and 40 mm/h in a cold crucible with 130 mm diameter

Table 14.6 Effective distribution coefficient of Y₂O₃ in the ZrO₂-Y₂O₃ system in PSZ

2.5	1.04 ± 0.01	1.07 ± 0.01	–
3	1.006 ± 0.007	1.025 ± 0.006	1.02 ± 0.02
3.5	1.150 ± 0.009	1.023 ± 0.005	1.027 ± 0.007
4	0.98 ± 0.09	1.001 ± 0.008	1.002 ± 0.009
5	1.03 ± 0.01	–	–
8	1.041 ± 0.007	–	–

Therefore, the most appropriate conditions for the preparation of large, smooth-faceted PSZ crystals are growth rate about 10 mm/h with enlarged bottom thermal shield. Studies of the chemical composition of the crystals showed that microcontaminants from the starting materials are segregated during growth of PSZ crystals in the same way as for CZ crystals. Decreasing the crystallization rate results in a decrease in contaminant concentrations compared with in the initial mixture [14.185]. The distribution of the main components of the solid solution (at crystallization rates of 3–40 mm/h) is fairly uniform, the value of K_{eff} Y₂O₃ in ZrO₂ being close to 1 [14.186] (Table 14.6).

Investigation of the crystal phase composition of as-grown crystals (growth rate 3–10 mm/h) by Raman spectroscopy revealed that molten ZrO₂ was m-phase; crystals containing 2 mol % Y₂O₃ were a mixture of m- and t-phases; crystals containing 2.5 mol % Y₂O₃ contained small m-phase regions, the larger part of the crystal being t-phase; at concentration range 3–5 mol % the crystals were t-phase; at Y₂O₃ concentration of 8–35 mol % the crystals were constituted by a cubic solid solution of fluorite structure [14.185, 186]. X-ray diffraction patterns of powdered samples prepared from PSZ crystals (growth rate 3–10 mm/h) showed that the m-phase is present in crystals containing 2.0–3.5 mol % Y₂O₃ while only the peaks of a highly symmetric phase are present in the pattern of crystals containing 4.0–5.0 mol % Y₂O₃. Apparently, t→m transformation occurred under powdering. Analysis of the same powders by Raman spectroscopy has confirmed that such a transformation in fact took place, indicated by the occurrence of the m-phase in powdered samples containing up to 3.5 mol % Y₂O₃. Differences in the phase composition of bulk and powdered samples show that X-ray diffraction analysis of powders more appropriately reflects the phase composition of materials subjected to intensive mechanical impact, while Raman spectroscopy allows a more detailed determination of the phase composition of bulk crystal samples. It

was shown that PSZ crystals grown in a CC of 130 mm in diameter are not sharply quenched, therefore they contain the t-phase as well as the t'-phase, and so the m-phase appears upon mechanical impact [14.186]. The incorporation of admixtures (oxides of Ce, Nd, Tb, Co, etc.) was also shown to influence the number of fractures [14.189–191].

The shape of the crystal growth surface precisely reflects the microstructure of the material, which is influenced by the composition as well as crystallization and annealing conditions. Scanning electron microscopic studies of the as-grown crystals showed that the crystal surface morphology is influenced by the stabilizing oxide concentration in the solid solution [14.185, 186, 189, 191]. Microphotographs of the as-growth crystal surfaces with different content of the stabilizing oxide (Y₂O₃) are shown in Fig. 14.18.

Relief of the growth facets of pure ZrO₂ crystals which had undergone a t→m transformation is typical for martensitic transitions (Fig. 14.18a,b). This transition is accompanied by a significant volume change (up to 5 vol. %) and causes fracturing. A regular microcrack network in the form of rhombs can be clearly seen in Fig. 14.18a. The cracks of each subset are apparently parallel to each other and the angle of intersection is close to 30°. Microcracks can be also seen on the growth surface of ZrO₂–2.0 mol % Y₂O₃ samples (Fig. 14.18c,d), but these microcracks are sufficiently shorter and many of them are warped. Both the elements of the above-described structure and the so-called *tweed* structure characteristic of samples with higher Y₂O₃ content can be seen on the surface. *Tweed* structure is characterized by element intersection angle close to 80–90°. The surface of crystals containing 2.5 mol % Y₂O₃ (Fig. 14.18e,f) is practically devoid of cracks, while the elements of the *tweed* structure occupying the larger part of the crystal surface can be clearly seen. However, only isolated elements of the *tweed* structure are present in some regions of the crystal surface (Fig. 14.18f). The existence of two characteristic

types (type 1 and type 2) of growth surface was detected for ZrO_2 crystals containing 3.0 mol % Y_2O_3 (Fig. 14.18g–j). Type 1 is characterized by *smooth* facets (Fig. 14.18g), while type 2 is characterized by *matted* facets (Fig. 14.18h,i). The boundary of the smooth and matted facets is shown in Fig. 14.18j.

Surface morphology of any of these types may be characteristic either for all facets of the crystal block or only for some of them, being present as an individual facet. The surface of type 1 comprises a rather regular structure, which is similar to the *tweed* one. It consists of tiny elongated rectangles (1–10 μm in length and 0.5–3 μm in width) grouped parallel to each other. The angle of orientation of groups relative to each other is close to 80–90°. The surface of type 2 has a more pronounced relief than the one described above and consists of parallel convex rectangles, which are larger than the elements of type 1 structure (up to 50 μm in length and > 5 μm in width). More pronounced relief of the structure forms the matted appearance of the facet. Figure 14.18 clearly shows that smaller structural elements with sizes characteristic of the smooth (type 1) surface coexist with larger surface elements on type 2 surfaces.

Matted surfaces occur in the central and lower part of the crystal bulk, their appearance being dependent on the melt volume and crystal length. At the same time, single-crystalline blocks are often accreted by these facets, so separation of such blocks sometimes leads to destruction of the crystals. It seems that this process is influenced by cooling conditions during crystal growth, which determine the phase composition and microstructure of the crystals. The absence of matted facets on the crystal surface at growth rate of 3 mm/h is worth mentioning. Practically, large crystals are no growing together. There are few such crystals in the ingot, and stress is relieved mainly on the block boundaries and partly in the block volume. The latter process results in crystal fracturing. The matted crystal surface is formed if the initial melt contains significant quantities of contaminants with K value much lower than 1. However, such surfaces differ from that described above by the presence of a characteristic tarnish of the segregated admixtures (Fig. 14.19).

Further increase of the stabilizing oxide concentration results in the appearance of various types of island structures; namely, islands consisting of parallel structural elements without perpendicular crossing appear on a *tweed* structure background in the case of ZrO_2 containing 3.5 mol % Y_2O_3 (Fig. 14.20a,b).

Crystals containing 4.0 mol % Y_2O_3 are characterized by a smooth unstructured surface on which small

Fig. 14.18a–h Morphology of as-grown facets of PSZ crystals of $(1-x)\text{ZrO}_2$ - $x\text{Y}_2\text{O}_3$ mol % compositions (**a,b**) $x = 0$; (**c,d**) $x = 2.0$; (**e,f**) $x = 2.5$; (**g,h**) $x = 3.0$

islands with a pronounced microstructure occur very rarely (Fig. 14.21). The appearance of an island structure can be indicative of incompleteness of the phase transitions occurring during the cooling of the crystal. As a result, Y_2O_3 is unevenly redistributed between two t-phases at temperatures corresponding to the two-phase region of the phase diagram. It is obvious that phases

Fig. 14.19 Surface of facets of ZrO_2 -3 mol % Y_2O_3 grown at 3 mm/h with SiO_2 inclusions (magnification 1700 \times)

Fig. 14.21 Surface of facets of ZrO_2 -4 mol % Y_2O_3 grown at 10 mm/h

with different Y_2O_3 content can differ in microstructure.

Nanostructure of ZrO_2 -3 mol % Y_2O_3 crystals was studied by high-resolution transmission electron microscopy (TEM) as well as by x-ray analysis. The latter method was used to estimate the size of coherent scattering regions according to the broadening of the diffraction reflexes [14.112, 114, 115, 186]. A model of ordered domain colonies occupying all the volume of the crystal at the minimum of deformation energy was proposed [14.112]. TEM studies of the ZrO_2 -3 mol %

Y_2O_3 crystal revealed the presence of colonies formed by *parquet* structure domains (30–100 nm in width, 400–800 nm in length) (Fig. 14.22).

Laminated structure with a period of about 10 nm is observed in the colonies, indicating the presence of a lamellar domain structure in each colony. Their size is estimated to be (0.1–0.5) \times (10–20) nm. An estimate of the coherent scattering region size (D) in the ZrO_2 -3 mol % Y_2O_3 crystal by X-ray structure analysis yields a value of 87–310 nm, which corresponds rather well to the above estimates of the colony size. A scanning electron microscopic study of the crystal surface microstructure at 25 000 \times amplification allowed estimation of the size of the smallest structural elements. The width was estimated to be 70–300 nm and the length was estimated to be 300–900 nm. These estimated values are close to the sizes of colonies observed during the TEM study. Therefore, the microstructure of as-grown facet of the crystals reflects the inner crystal structure (the structure of colonies). Research on

Fig. 14.20a,b Surface of facets of ZrO_2 -3.5 mol % Y_2O_3 grown at 10 mm/h. (a) 1900 \times ; (b) 5000 \times

Fig. 14.22 Nanostructure of ZrO_2 -3 mol % Y_2O_3 crystal grown at 10 mm/h

Fig. 14.23 Nanostructure of ZrO_2 –2.5 mol % Y_2O_3 crystal grown at 10 mm/h

the nanostructure of ZrO_2 –2.5 mol % Y_2O_3 crystals showed that the formation of the domain structure just begins at this Y_2O_3 concentration (a system of parallel domains with some elements of the tweed structure is formed) (Fig. 14.23).

Only isolated regions with nonpronounced domain structure were detected in ZrO_2 –4 mol % Y_2O_3 crystals (Fig. 14.24).

This corresponds to the results of research on the microstructure of growth surface of PSZ crystals as determined by their composition. The doping of PSZ crystals with additional admixtures in small quantities (≈ 0.1 mol %) affects the microstructure and mechanical properties of the crystals [14.189, 191]. These studies revealed that sample breaking strength is connected with the structure of the crystal surface, which reflects the microstructure of layers adjacent to the surface.

The oxygen-isotope method was used to study the peculiarities of oxygen redistribution during formation

Fig. 14.24 Nanostructure of ZrO_2 –4 mol % Y_2O_3 crystal grown at 10 mm/h

and stabilization of the structure of substitutional solid solutions $\text{Zr}_{1-x}^{+4}\text{Y}_x^{+3}\text{O}_{2-0.5x}^{-2}\text{V}_{0.5x}^0$ and further annealing of the crystals under various gas atmosphere. The mobility of oxygen was shown to depend on the chemical composition of the crystal and the conditions of heat treatment. The existence of correlation between oxygen mobility in PSZ crystals and their electrical and mechanical properties was confirmed [14.192]. It was also shown that maximum oxygen mobility is found in PSZ crystals containing 2.5–4.0 mol % Y_2O_3 . The optimal composition range of PSZ crystals ensuring the nanocrystalline structure, high mechanical characteristics, and high oxygen mobility was found by physicochemical methods to be ZrO_2 –2.5–4.0 mol % Y_2O_3 .

Significant anisotropy of strength properties (elastic characteristics, threshold values of strength, deformation properties, specific fracture energy, fracture strength, and hardness) was detected in studies of the dependence of these properties on Y_2O_3 concentration, presence of additives, growth rate, crystallographic orientation, and heat treatment conditions. It should be mentioned that stabilizing oxide concentration exerts a determining influence on strength properties [14.116, 181, 193–197]. The following high values of strength properties were determined for PSZ crystals: dynamic modulus of elasticity of 400–500 GPa, ultimate compression strength of 4000 MPa, ultimate bending strength of 1600 MPa, fracture toughness of $15 \text{ MPa m}^{0.5}$, and hardness of 15 GPa.

Results of the studies of the tribological properties of PSZ crystals are presented in [14.195–197].

Fig. 14.25 Effect of Y_2O_3 concentration on wearing intensity (J) and friction coefficient (f)

The main tribotechnical properties and the mechanism of wearing of the PSZ crystals were determined in experiments including x-ray and electron microscopic analyses of friction surfaces. PSZ crystals containing

2.5–4.0 mol % Y_2O_3 were the most wear resistance. The intensity of wear was $(2.5\text{--}4.3) \times 10^{-9}$, the friction coefficient was 0.32–0.34, and microhardness was 11.8–15.08 GPa (assessed with instrumental steel U10A as counterbody) (Fig. 14.25).

The predominant wear mechanism of the PSZ crystals was shown to be a two-stage mechanical (fatigue) mechanism involving the destruction of the surface layer of secondary structures formed upon friction with subsequent destruction of deeper layers of the bulk material. The results obtained show that synthesis of high-strength fracture-proof materials by directional crystallization of melt requires consideration of many factors: the K_{eff} values of the additives used, growth rate, temperature gradients in the melt, the nature and concentrations of the stabilizing oxide and the third additive, and cooling and annealing conditions.

PSZ crystals possess a number of properties giving them advantage over metals and high-strength dielectric materials (including ceramics). Due to their lack of grain boundaries PSZ crystals are characterized by high strength (comparable to the strength of metals), fracture toughness, and hardness. They are also char-

Fig. 14.26 Technical articles and components fabricated from PSZ crystals. PSZ crystals (top left); cutting elements, rolls and grinding tool fabricated from PSZ (top right); medicine scalpels with cutting edge from PSZ (bottom left); wire drawing die with insert from PSZ (bottom right)

acterized by low friction coefficient and high abrasive wear resistance, and high resistance to acids, alkali, and water vapor. Deterioration of mechanical characteristics of PSZ crystals placed in oxidizing atmosphere at high temperatures (up to 1400 °C) is much less pronounced than that of metals (which are intensely oxidized) or construction ceramics, which are prone to recrystallization. Besides, the mechanical properties of the crystals are improved upon temperature decrease (at −140 °C the improvement amounts to 70%). Such materials can be used to produce details of appliances functioning under extreme conditions: at high mechanical loadings, in aggressive media, at elevated temperatures, without lubrication, etc. Such appliances include bearings, support prisms, guide plates, and motor valves. Due to the existence of domain nanostructure in PSZ crystals and high mechanical strength of these crystals they may be used in the manufacturing of instruments with very sharp cutting edges, for example, high-quality medi-

cal scalpels and instruments for precision machining of various materials (metal, wood, glass, crystals, etc.).

The biological inertness of this material [14.183, 198, 199] enables its use in the manufacturing of implants for medicine. Comparative mechanical and biomedical tests were performed for PSZ crystals, CZ crystals, PSZ ceramics, and Al₂O₃ single crystals [14.182]. PSZ crystals were shown to be somewhat stronger than other materials and displayed the highest fracture toughness. Studies on implants made of ZrO₂-based materials showed that these implants neither provoke an inflammatory reaction in tissues nor cause pathological changes in the internal organs of animals. The results of investigations show that PSZ crystals can be used as a material for various implants. Some articles manufactured from PSZ crystals are shown in Fig. 14.26 to give examples of practical applications of this material.

14.4 Glass Synthesis by Skull Melting in a Cold Crucible

In this section some questions about using SM technique for glass synthesis will be analyzed. Use of this method is justified if the synthesis of a specific type of glass by traditional methods is impossible or very difficult. These glass types include:

- Optical and laser glasses for which high chemical purity is required; for example, in glasses for fiber-optical communication lines the content of transition-metal contaminants must not exceed 10^{−5}–10^{−6} wt %
- Glasses prepared from highly reactive melts and/or materials capable of interacting with the crucible material
- High-temperature glasses of various compositions which must be synthesized at temperatures exceeding 1600 °C.

Let us analyze the peculiarities of the use of this method for glass synthesis.

Glass is an amorphous material, undergoing a smooth transition from solid state to glass-like state upon heating. Glass-forming melts differ from other oxide melts by their high viscosity (depending on the melt composition, the viscosity may be several orders of magnitude higher than that of typical oxide melts) and a smooth temperature dependence of viscosity and electric conductivity. Besides, the absence of a solid–liquid phase transition and the corresponding dramatic change

in electric conductivity enhance the phase stability of the melt and make keeping of the melt in a stationary state easier. That is why in the case of induction melting in the cold crucible the skull consists of a thin layer of initial powdered mixture adjacent to crucible walls and a layer of solid glass, the thickness of the latter layer being influenced by the temperature distribution in the melt.

Various types of crucibles are used according to the composition of a specific glass type. Synthesis of silicate glasses was performed in water-cooled quartz crucibles [14.10, 11]. As quartz is a typical dielectric, effective supply of the alternating electromagnetic field energy to the melt without losses in the crucible material is enabled. The use of such crucibles imposes considerable limitations on the temperature of glass synthesis. Other drawbacks of quartz crucibles are the impossibility of repeated use and a requirement for stringent control of the melt temperature to avoid the risks of crucible destruction and water getting into the melt. Metallic crucibles for glass synthesis also have some peculiarities. Aluminum is the preferred crucible material. Beside individual oxides, salts (carbonates, nitrates, oxalates, etc.) are often used as starting materials for glass synthesis. Upon thermal decomposition of salts, interaction of the decomposition products with the crucible material and transfer of small quantities of crucible material into the melt may occur. In the case of aluminum

crucibles, a thin layer of Al_2O_3 present on the surface of aluminum prevents the heterogeneous chemical reactions. Besides, Al_2O_3 is often present in glasses and therefore embedding of small amounts of Al_2O_3 into the melt does not cause a significant change in the properties of glass. Aluminum oxide is an optically inactive admixture, so its presence does not influence the optical properties of glass. Metallic crucibles must be dismountable in order to ensure quick extraction of the glass block for further annealing. The use of combined crucibles, i. e., metallic crucibles with thin-walled quartz crucibles inserted into them, has also been reported [14.26].

In the case of glass synthesis, the initial melt volume cannot be created by introducing small pieces of a metal directly into the initial mixture, because this would lead to contamination of the melt by metal and the reduction products dispersed in the melt volume. The high viscosity of glass-forming melts leads to a dramatic decrease in the metal burning-out rate [14.31]. Start melting is usually performed by placing a quartz ampoule filled with pieces of graphite or low-resistance Si into the fusion mixture. Afterwards the ampoule is removed from the melt. To make start melting easier and to prevent the evaporation of low-melting-point components, one should first melt the low-melting-point components and then introduce the refractory ones into the melt; for example, glass synthesis in the system $\text{Li}_2\text{O}-\text{Al}_2\text{O}_3-\text{SiO}_2-\text{ZrO}_2$ was begun with the melting of the $\text{Li}_2\text{O}-\text{SiO}_2$ composition, which melts at $1100-1200^\circ\text{C}$ [14.200].

Homogenization of the melt is an important technological stage of high-quality optical glass synthesis. Complicated physicochemical processes connected with the melting of individual components of the fusion mixture and the occurrence of solid-phase chemical reactions and reactions in the melt are finished at this stage. Nonuniform temperature distribution in the melt exerts a significant influence on the dissolution of the fusion mixture components not yet involved in chemical reactions and the removal of the previously formed gas bubbles. At first, bubbles are removed from the maximum temperature zone, which is situated at a distance of 10–20 mm from the crucible walls (Fig. 14.3). Intensive convection in the melt, which promotes the removal of gas bubbles and leveling of the chemical composition of the melt, is an important consequence of the existence of high temperature gradients in the melt. Mechanical stirring by a water-cooled stirrer or by gas bubbling through the melt is used to intensify these processes [14.11, 31]. These methods are used in

combination with the melt temperature increase, which causes a decrease in viscosity and an increase in the rate of convective mass transfer.

After glass synthesis in the CC, annealing cannot be performed in the same crucible because, when the temperature of the melt being cooled reaches a value determined by the temperature dependence of the conductivity, the melt ceases to absorb the energy of the RF electromagnetic field. After this, intensive cooling of the glass by the water-cooling crucible walls and glass fracturing occurs. Therefore a method of glass extraction from the crucible with subsequent annealing in the furnace is essential. One of the methods consists of pouring the melt into a mold and further annealing of the glass. However, the risk of contamination of the central part of the glass block by bubbles and nonmolten particles of the fusion mixture from the periphery of the block is very high during this operation. Another method consists of extracting the glass block at a specific temperature, which is determined experimentally for every glass composition. The periphery of the glass block being cooled much quicker than the central part, the extraction temperature must be high enough to prevent fracturing of the peripheral part, but not too high, otherwise softening of the peripheral part and leakage of the viscous glass mass may occur due to heating by the inner hot part. In the case of glass synthesis in cooled quartz crucibles, a crucible with glass is simply transferred into the annealing furnace. Thin-walled crucibles are used to prevent glass fracturing caused by the difference of glass and quartz thermal expansion coefficients. The quartz crucible fractures and exfoliates during annealing, while the glass block remains a monolith.

A significant factor limiting the use of this method for the synthesis of glass with enhanced crystallization ability should be mentioned. The presence of the skull increases the possibility of glass crystallization because the initial mixture crystalline particles are ready nuclei contacting the melt directly. Under certain conditions initial mixture particles may provoke the crystallization of the whole glass volume. The possibility of preparation of glasses with enhanced crystallization ability in the cold crucible depends on a multitude of factors: melt volume, thickness of the viscous glass layer (which is determined by the power released in the melt as well as by the temperature dependence of the viscosity and electrical conductivity of the melt), the cooling rate of melt, and the rates of nucleation and crystal growth. Therefore quantitative assessment of this possibility is very difficult. As for qualitative analysis, it is clear that the crystal nuclei must not be able to grow through the

Table 14.7 Thermal expansion coefficients (K_{te}) and transformation (T_l) and softening (T_g) temperatures in glass of the $\text{La}_2\text{O}_3\text{--Al}_2\text{O}_3\text{--SiO}_2$ system [14.201]

Composition (mol%)			K_{te} (20–800 °C) ($\times 10^{-7}$, °C $^{-1}$)	T_g (°C)	T_l (°C)

68.3	25.6	6.1	39.1	905	860

whole melt volume while the temperature of the melt being cooled is in the range of possible crystallization. Otherwise, a block of crystallized glass is formed.

14.4.1 Refractory Glasses of the $\text{R}_2\text{O}_3\text{--Al}_2\text{O}_3\text{--SiO}_2$ ($\text{R} = \text{Y}, \text{La}$, Rare-Earth Element) Systems

Investigation of the properties of glasses formed in this system was performed by several research groups and showed that these glasses possess a combination of valuable properties [14.201–207]. High refractive indices and high mechanical strength combined with high deformation temperature, relatively small values of thermal expansion coefficient (K_{te}), very low electric conductivity, and extremely high resistance to the action of alkalis make these glasses promising materials for use at high temperatures in chemically aggressive media. Besides, glasses formed in this system are devoid of oxides of alkaline or alkaline-earth metals and can be structurally different from traditional alkaline glasses. This undoubtedly makes them objects of scientific interest; for example, a nuclear magnetic resonance study of glasses of the $\text{SiO}_2\text{--Al}_2\text{O}_3\text{--Y}_2\text{O}_3$ system revealed the presence of tetra-, penta-, and hexacoordinated Al^{3+} ions in the glass structure, as well as a rather complicated structure of the silicon–oxygen framework [14.208].

Synthesis of glasses of the $\text{R}_2\text{O}_3\text{--Al}_2\text{O}_3\text{--SiO}_2$ ($\text{R} = \text{Y}, \text{La}$, rare-earth element) systems was performed by SM in a CC [14.201, 203]. Synthesis was performed under air at temperature of $\approx 2000^\circ\text{C}$ in water-cooled metal crucibles of 90–120 mm in diameter. Pieces of graphite were used for initial melting. The glass blocks obtained had a mass of 2–6 kg (depending on the crucible size) and did not contain any inclusions or bubbles. The practically important values of the K_{te} and characteristic temperatures for glasses of various compositions are presented in Table 14.7.

High values of the softening temperatures (855–920 °C) combined with relatively low K_{te} values ($33.7\text{--}64$) $\times 10^{-7}$ make these glasses promising materials for use in electrovacuum technologies for welding and sealing of W and Mo. Apart from being convenient for the preparation of relatively large quantities of glass, the SM technique proved to be very convenient for studies on glass formation in various systems. This method allows obtaining a range of samples of various compositions in one experiment. The glass-formation range in the system $\text{La}_2\text{O}_3\text{--Al}_2\text{O}_3\text{--SiO}_2$ was studied in [14.201]. Samples for these investigations were prepared as follows: first, a two-component mixture $\text{Al}_2\text{O}_3 + \text{SiO}_2$ of predetermined composition was melted in the cold crucible. After keeping of the melt at the temperature 1800–2000 °C for 1 h, a mixture

Fig. 14.27 Glass-forming region in the $\text{La}_2\text{O}_3\text{--Al}_2\text{O}_3\text{--SiO}_2$ system at different synthesis temperatures: 1 – 1600 °C, 2 – 2000 °C; (○ – glass, ● – sintered, ⊗ – surface crystallized) (after [14.201])

of SiO₂ + La₂O₃ with a predetermined composition was added in small (30–50 g) portions. After the addition of each portion the melt was homogenized for 10 min and then drops of the glass mass weighing 1–3 g were extracted with a quartz rod and quenched on a water-cooled metal surface. After this evaluation of the chemical compositions of the samples by electron probe microanalysis, microscopic analysis and X-ray diffraction analyses were performed. The results of the study compared with the literature data available are presented in Fig. 14.27.

The increase of the glass synthesis temperature to 2000 °C evidently leads to a considerable broadening of the glass-forming range in this system. Thus, at a SiO₂ content of 65–75 mol % the addition of only \approx 2 mol % of La₂O₃ results in the formation of transparent glass. It is also worth noting that this system allows obtaining glasses with a SiO₂ content less than 50 mol %. These glasses are of interest for structural research because a continuous silicon–oxygen framework cannot exist in them.

Another interesting feature of the glasses of the R₂O₃–Al₂O₃–SiO₂ system is the possibility of obtaining glasses with extremely high concentrations of rare-earth element ions, in particular the Nd³⁺, Yb³⁺, and Tb³⁺ ions. It is impossible to obtain such glasses using conventional alkaline glass matrices. The weight of glass blocks obtained amounted to 5 kg, and the rare-earth metal-ion content amounted to 10²² cm^{–3}. The properties of some of the glasses synthesized are presented in Table 14.8.

The study of the luminescence spectra of the Sm³⁺ and Eu³⁺ ions present in lanthanaluminate glass was performed using the method of selective laser excitation of luminescence and revealed the absence of microphases with drastically different symmetries in the surroundings of the active ions, i. e., the activator

ions in the glass were not segregated [14.209, 210]. Glasses synthesized in cold crucibles at high temperatures are characterized by low content of hydroxyl groups OH[–], even without using special dehydration methods (the peak value of absorption coefficient at the wavelength 3 μ m is about \approx 3–4 cm^{–1}) [14.211]. Glasses with Nd³⁺ concentration up to 1.1 \times 10²² cm^{–3} are characterized with peak absorption coefficients of 290, 130, 150, and 40 cm^{–1} at wavelengths of 590, 745, 810, and 890 nm, respectively. High thermophysical and mechanical characteristics of such glasses (Table 14.8) combined with their stability at high temperatures make them promising materials for thin, optically dense, selective filters. Glasses with a high content of Tb³⁺ ions are also of considerable practical interest. This ion possesses magneto-optical activity, that is, it can alter the phase of linearly polarized light when magnetic field is applied. Measurements of the magneto-optical properties of the Tb₂O₃–Al₂O₃–SiO₂ glass containing 9.5 \times 10²¹ Tb³⁺ ions/cm³ showed that the Verdet constant equals –0.33 min/Oe cm at the wavelength of 630 nm. Such a high value of the Verdet constant combined with the high value of the laser damage threshold (1.7 \times 10⁹ W/cm²) and high heat conductivity opens wide perspectives for the use of this glass in various Faraday rotator devices in high-power laser systems.

14.4.2 Immobilization of Radioactive Waste in Stable Solid Blocks

During the last few years the SM method was widely applied for the immobilization of liquid and solid wastes (including radioactive waste) in stable solid blocks (phosphate and borosilicate glasses, mineral-like compositions) [14.212]. Improvement of the efficiency of radioactive waste neutralization is one of the main

tasks of the atomic power generation industry. Waste recycling is a complex problem. It includes various technological stages (preparation and delivery of waste for recycling, melting, pouring into containers, collection and processing of the gases released, etc.). The melting unit is the most important element of such systems. Until recently all existing programs of waste vitrification relied on the use of traditional melting furnaces with hot crucibles, working in the 1100–1150 °C temperature range. Phosphate and borosilicate glasses are commonly used as matrices for waste immobilization. However, the low operate temperatures of such furnaces impose considerable limitations on the vitrification process. The use of a CC enables working at higher temperatures

and removes the restrictions inherent to conventional melting units. Thus, higher temperatures provide broad possibilities for the design and application of new glass-forming and crystalline matrices for waste immobilization, including the possibility of introducing a higher concentration of waste matter into the matrices already being used, and processing of a wider range of waste matters (for example, heat-insulating materials) without the introduction of fluxing additives [14.213]. Other advantages of this technology include the small dimensions of the melting unit and high productivity of waste processing. Research and industrial *cold-crucible* systems are widely used nowadays in Russia, the USA, France, Germany, Italy, and South Korea [14.214].

14.5 Conclusion

This chapter on the application of skull melting of dielectric oxide materials in a cold crucible has illustrated the dynamic development of the method, which provides a basis for industrial-scale technologies as the development and manufacturing of the corresponding equipment has increased. The range of materials synthesized by means of this technique has

become increasingly wide. Development of the technique for growth of PSZ crystals and nuclear waste vitrification can be pointed out as two of the most promising directions. Nevertheless, it is apparent that the potential of the method has not been exhausted, particularly in the field of single-crystal growth of refractory compounds.
